Biosynthesis of Heparin

ASSAY AND PROPERTIES OF THE MICROSONAL N-ACETYL-D-GLUCOSAMINYL N-DEACETYLASE*

(Received for publication, August 28, 1979)

Johan Riesenfeld, Magnus Höök, and Ulf Lindahl

From the Department of Medical and Physiological Chemistry, Swedish University of Agricultural Sciences, The Biomedical Center, S-751 23 Uppsala, Sweden

In a previous study on heparin biosynthesis, incubation of a mouse mastocytoma microsomal fraction with UDP-N-acetyl-D-glucosamine and UDP-D-glucuronic acid resulted in the formation of two nonsulfated polysaccharides, one of which was fully N-acetylated whereas the other contained about equal amounts of N-acetylated and N-unsubstituted glucosamine residues. In the presence of 3'-phosphoadenylyl sulfate the latter species was converted into heparin through a series of reactions initiated by sulfation of the unsubstituted amino groups (Hook, M., Lindahl, U., Hallén, A., and Backström, G. (1975) J. Biol. Chem. 250, 6065-6071).

Incubation of the fully N-acetylated polysaccharide with microsomal enzyme resulted in partial N-deacetylation, as shown by the formation of a product susceptible to deamination with nitrous acid. Characterization of the deamination products by gel chromatography suggested that the N-acetyl groups had been attacked in a random fashion. An assay for the reaction required Mn2+ ions and had a pH optimum recovered by extraction with ethyl acetate and quantitatively labeled acetate from a N-[3H]acetylated heparin precursor polysaccharide; the released [3H]acetate was recovered by extraction with ethyl acetate and quantified by liquid scintillation counting. The rate of acetate release was linear with time and directly proportional to the concentration of microsomal enzyme. The reaction required Mn2+ ions and had a pH optimum between 6.0 and 6.5. Salts were inhibitory at relatively low concentration (50% inhibition at 50 mM NaCl concentration). Exhaustive incubation of the labeled substrate with microsomal enzyme caused release of 30 to 35% of the [3H]acetate groups originally present; this value could be increased only by reincubating the substrate after substitution of the N-unsubstituted 2-glucosamine residues with (unlabeled) acetyl groups.

Incubation of various labeled glycosaminoglycans with mastocytoma microsomal fraction showed that only polysaccharides structurally related to heparin (microsomal heparin-precursor polysaccharides, and, in addition, a N-desulfated, N-acetylated heparan sulfate) were susceptible to N-deacetylation. Other N-acetylated polysaccharides, such as hyaluronic acid, chondroitin sulfate, and dermatan sulfate were not attacked by the N-deacetylase.

Our knowledge regarding the biosynthesis of heparin de...
ml of 0.5% Na₂SO₄ in 10% aqueous methanol and 5 x 2 mCi of [H]acetic anhydride was added at 0°C over a period of 1 h. After the addition of 4 x 5 μl of unlabeled acetic anhydride the product was passed through a column of Sephadex G-25 equilibrated with 1 M sodium acetate, and desalted by dialysis against water. Final purification was obtained by ion exchange chromatography on DEAE-cellulose; the acetylated material, [³⁵C]PS-N₃H]Ac (ratio of H to C, 20:1 to 40:1, depending on preparation), was eluted at the same position as native PS-NAc. The purified [³⁵C]PS-N₃H]Ac was susceptible to degradation by heparitinase from F. heparinum (12), as shown by gel chromatography of the digestion products on Sephadex G-50; the major portion of the label appeared at the elution position of di- or tetrasaccharides. The N-acetylated species, [³⁵C]PS-NAc, was also obtained by substituting [³⁵C]PS-NAc for unlabeled N-acetyl groups. Since this product was available in much larger amounts than the native analog (see Fig. 1 in Ref. 3) it was used throughout this study, except where otherwise stated.

Additional heparin-related labeled polysaccharide preparations were obtained by chemical N-deacetylation of [³⁴C]PS-N₃O₅ and [³⁴C]PS-N₃O₅-PS-N₃O₅, followed by N-acetylation with unlabeled acetic anhydride, and by N-desulfation and N-deacetylation of heparan sulfate followed by N-acetylation with ¹⁴C/acetic anhydride. Hyaluronic acid, chondroitin 4-sulfate, and dermatan sulfate with ¹⁴C-labeled N-acetyl groups were prepared by limited N-deacetylation followed by reacetylation of the exposed amino groups with ¹⁴C/acetic anhydride. The procedure will be described in detail elsewhere. The labeled products had specific activities as shown in Table 1. Biosynthetically labeled chondroitin, containing D-[¹⁴C]glucuronic acid residues, was prepared as described previously (2) except that UDP-D-[¹⁴C]glucuronic acid was substituted for UDP-D-[¹⁴C]glucuronic acid.

*Percent of dry weight, not corrected for moisture or for losses during hydrolysis.
*Molar ratios with hexosamine as 1.0.
*Percent of total hexosamine. For experimental details, see Ref. 2.
*The ratio of glucosamine to total hexosamine was 1.0 for heparin and heparan sulfate.

**Fig. 1.** Representative disaccharide units of microsomal polymeric intermediates. In addition to the N-sulfated glucosamine residues shown in the figure, PS-NAc and PS-N/O-SO₅ also contain small amounts of N-acetylated glucosamine units. The occurrence of L-iduronic acid (10 to 20% of the total uronic acid) in PS-NAc was not recognized in a previous study (3), but has since been clearly demonstrated by more refined analysis (2). The intermediates, PS-NAc, PS-N₃H₃, PS-N₃O₅, and PS-N/O-SO₅ mentioned in the chronological order of formation during heparin biosynthesis, correspond to the chromatographic Fractions I, II, III, and IV, respectively, described in a previous publication (3). Fractions I to III appear fairly homogenous in ion exchange chromatography whereas Fraction IV (PS-N/O-SO₅) is markedly heterogeneous.

*Samples (15,000 cpm of H) were incubated according to the standard procedure (see “Materials and Methods”); 0.34 mg of microsomal protein was added/incubation (0.1 ml). The amounts of N-[³⁵H]Acetyl released could be increased further by prolonging the incubation time.
Chemical Modification of Polysaccharides—Selective N-desulfation of polysaccharides was performed by treatment of their pyridinium salts with dimethyl sulfoxide containing 5% water at 50°C for 90 min (13). Analysis of products showed that N-desulfation was incomplete (Table 1). N-Deacetylation was achieved by treatment with hydrazine in the presence of hydrazine sulfate (14) at 100°C for 45 min to obtain partial deacetylation. The reaction time was reduced to 20 min. Polysaccharides with N-unsubstituted hexosamine residues were N-acetylated by treatment with acetic anhydride (15).

Degradation of Polysaccharides with Nitrous Acid—Polysaccharides were treated with nitrous acid at pH 3.9 (Reaction B in Ref. 6, initially described by Shively and Conrad (16)). Under these conditions N-glucosamine residues with unsubstituted amino groups are converted to 2,5-anhydro-β-mannose units, with cleavage of the corresponding glucosaminic linkage (see also Ref. 17).

Assay of N-Acetylglucosaminyl N-Deacetylase—The assay procedure used was a modification of that employed in studies of the enzymatic N-deacetylation of chitin in Mucon rouxii (18). Reaction mixtures contained the following components in a total volume of 0.1 ml: 0.05 M 2-(N-morpholino) ethanesulfonic acid, pH 6.3; 10 mM MnCl₂; Η- and 14C-labeled polysaccharide substrate (14C]PS-N[3H]Ac, 5,000 to 10,000 cpm 'H); and enzyme (0.4 mg or less of microsomal protein in 2 ml of 0.05 M 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid, pH 6.3; 10 mM MnCl₂; 10 μl of 1 M acetic acid, and 0.2 ml of water were added. The [3H]acetate released was then separated from the polysaccharide by extraction with 3 x 1 ml of ethyl acetate, and quantified after addition of 6 ml of Dimilume (Packard Instrument Co.) by scintillation counting. Occasionally, the counted samples were contaminated with the polysaccharide substrate, due to inadequate separation of the organic and aqueous phases during the extraction procedure. Such contamination, resulting in erroneously high 'H values was revealed by the presence of 14C radioactivity, and the samples were eliminated. The standard error of duplicate assays was 53 cpm (70 observations), when the amount of released [3H]acetate ranged from 200 to 1000 cpm.

RESULTS

Release of ['H]Acetate from [14C]PS-N[3H]Ac—Incubation of the [14C]glucuronosyl- and N-['H]acetyl-labeled heparin precursor, [14C]PS-N[3H]Ac, with mast cell microsomes resulted in release of a 'H-labeled component that was extractable with acid ethyl acetate. On paper chromatography in Solvent A or Solvent B this component co-migrated with the cor-

![Fig. 2. Release of [3H]acetate during prolonged incubation of [14C]PS-N[3H]Ac with mouse mastocytoma microsomal fraction. [14C]PS-N[3H]Ac (1 x 10⁴ cpm 'H) was incubated with 8 mg of microsomal protein in 2 ml of 0.05 M 2-(N-morpholino)ethanesulfonic acid, pH 6.3, containing 10 mM MnCl₂. At the times indicated, aliquots of 10 μl were diluted to 100 μl with water and analyzed for released [3H]acetate as described under "Materials and Methods" (○—○). After 24 hr at 37°C, the incubations were digested with papain and the polysaccharide was reisolated (2) and incubated in a similar manner for another 24-h period (□—□). The arrows indicate additions of fresh enzyme (8 mg of microsomal protein).

Except for the salts added the incubations were carried out under standard conditions (see "Materials and Methods")

Biochemistry
Biosynthesis of Heparin

with nitrous acid, respectively. Chemical N-acetylation of [14C]PS-NH₃⁺, yielding [14C]PS-NAc, eliminated the susceptibility to nitrous acid (Fig. 6B). Incubation of this product with mastocytoma microsomal fraction restored the susceptibility to nitrous acid (Fig. 6B). Calculations (2) based on the gel chromatography pattern in Fig. 6B indicated that exhaustively incubated [14C]PS-NAc had 38% N-unsubstituted D-glucosamine residues; this value is in fair agreement with the amount of [3H]acetate lost during similar incubation of the doubly labeled substrate, [14C]PS-N²HAc (see above).

Treatment of partially N-deacetylated [14C]PS-NAc with nitrous acid should yield oligosaccharides with 2,5-anhydro-D-mannose units in reducing and D-[9C]glucuronic acid units in nonreducing position. In order to ascertain that the deamination products derived from the enzymatically deacetylated polysaccharide conformed to this pattern the tetrasaccharide fraction, isolated by gel chromatography (Fig. 6B), was digested with β-glucuronidase. Analysis of the digestion products by gel chromatography on Sephadex G-15 showed, according to prediction, that the tetrasaccharide had been converted to free D-[9C]glucuronic acid and a labeled trisaccharide, presumably N-acetyl-D-glucosaminyl-D-[9C]glucuronosyl → 2,5-anhydro-D-mannose (Fig. 7). Incubation with microsomal enzyme followed by nitrous acid treatment gave the same degradation pattern irrespective of whether chemically N-acetylated [14C]PS-NH₃⁺ or native [14C]PS-NAc was used.

![Graph](http://www.jbc.org/)
as substrate. Taken together with the observed liberation of $[^3H]$acetate from $[^{14}C]$PS-N$[^{3H}]$Ac these results demonstrate the presence in the mastocytoma microsomal fraction of an enzyme that removes N-acetyl groups from internal positions of the heparin precursor polysaccharide, PS-NAc, leaving N-unsubstituted D-glucosamine residues. Further support for this conclusion was obtained by chromatography of $[^{14}C]$PS-N$[^{3H}]$Ac on DEAE-cellulose, before and after incubation with microsomal enzyme. The incubation product showed a lower $^{14}C/[^3H]$ ratio and a lower net negative charge than the substrate (Fig. 8), in agreement with the postulated N-deacetylation and exposure of positively charged amino groups.

The action of the N-deacetylase was studied with regard to the mode of propagation of enzymatic attack along the polysaccharide chain. Samples of $[^{14}C]$PS-NAc were incubated with microsomal N-deacetylase for varying periods of time and the products were reisolated, treated with nitrous acid, and analyzed by gel chromatography on Sephadex G-100 (Fig. 9). The oligosaccharides formed on deaminative cleavage of exhaustively N-deacetylated material consisted largely of tetra-, hexa-, and octasaccharides (Fig. 6B), and appeared as a retarded peak (elution volume about 67 ml) on Sephadex G-100 (Fig. 9). The fully N-acetylated (and thus nitrous acid-resistant) substrate was essentially excluded from the same gel. If the N-deacetylase operated strictly from one end of the polysaccharide chain to the other, the most retarded peak would be prominent already after short periods of incubation. However, the deamination products showed progressively diminishing size with increasing time of N-deacetylation, without any apparent initial formation of small oligosaccharides (Fig. 9). These results are consistent with a process of random attacks by the N-deacetylase at internal positions of the polysaccharide chains.

Incubation of mastocytoma microsomal fraction with UDP-$D$-glucuronic acid and UDP-$N$-acetyl-$D$-glucosamine yields a partially (about 50%) N-deacetylated polysaccharide product, PS-NH$_3$ (3). The mechanism behind this incomplete deacetylation of an endogenous, membrane-bound polysaccharide has been unclear. Exhaustive incubation of exogenous $[^{14}C]$PS-N$[^{3H}]$Ac with microsomal enzyme similarly removed only a fraction, about 30 to 35%, of the N-$[^{3H}]$acetyl groups. Only a minor portion of the remaining groups was released on reisolation and reincubation of the polysaccharide (Fig. 2). These results raised the question whether acetyl groups at certain predetermined positions in PS-NAc were resistant toward the enzyme. That this was not the case was demonstrated by the following experiment. After exhaustive incubation of $[^{14}C]$PS-N$[^{3H}]$Ac with microsomal enzyme, as described in the legend to Fig. 2, the labeled polysaccharide was reisolated and used as substrate in the standard assay procedure, either directly or after substitution of free amino groups with unlabeled acetyl groups. While only 2% of the $[^{3H}]$acetyl groups were released from the once deacetylated polysaccharide, this figure increased to 11% after acetylation of the free amino groups, the latter value being similar to that obtained with the starting material, $[^{14}C]$PS-N$[^{3H}]$Ac. These observations suggest that the resistance of N-$[^{3H}]$acetyl groups was due to the presence of unsubstituted amino groups in the vicinity. The N-deacetylation process is thus self-limiting and comes to a stop when about half (as in PS-NH$_3$) or less of the N-acetyl groups have been removed.

Substrate Specificity—The substrate specificity of the microsomal N-deacetylase was studied in three types of experiments. First, various polysaccharides containing $^3$H-labeled N-acetyl groups were incubated with the enzyme and liberated $[^3H]$acetate was determined (Table II). Significant release of $[^3H]$acetate occurred only with heparin-related polysaccharides, such as $[^{14}C]$PS-N$[^{3H}]$Ac and a N-$[^{3H}]$acetylated derivative of heparan sulfate; $[^{3}H]$hyaluronic acid, $[^{3}H]$chondroitin 4-sulfate, and $[^{3}H]$dermatan sulfate were all inactive as sub-

![FIG. 8. Chromatography of $[^{14}C]$PS-N$[^{3H}]$Ac on DEAE-cellulose before (C-○-○, $^3$H; △-△-△, $^{14}C$) and after (○-○-○, $^3$H; △-△-△, $^{14}C$) incubation with mastocytoma microsomal fraction. Incubation was carried out as described in the legend to Fig. 7. ---, concentration of LiCl in the elution gradient (see Ref. 2 for further details regarding the chromatography). The arrow indicates the peak elution position of standard hyaluronic acid. The $[^3H]$acetate released during the incubation was removed during subsequent reisolation of the polysaccharide.](http://www.jbc.org/doi/10.1074/jbc.926000319)
Strategies. Secondly, variously labeled polysaccharides, including chondroitin (containing D-[14C]glucuronic acid residues), hyaluronic acid (containing N-2H-acetylated groups), [14C]PS-NAc, [14C]PS-NH2, N-desulfated, N-acetylated [14C]PS-NSO3-, and [14C]PS-N/O-PSO3-, and the N-[3H]acetylated heparan sulfate derivative, were incubated with microbial N-deacetylase for 24 h, and were then reisolated, treated with nitrous acid, and subjected to gel chromatography on Sephadex G-100 or (only with incubation products of [14C]PS-NH2-+) Sephadex G-25. Depolymerization of incubated samples, indicative of N-deacetylation, was observed in all polysaccharides except the labeled chondroitin and hyaluronic acid.1 Nonincubated controls resisted deamination, except [14C]PS-NH2+, which, as expected, showed the same content of N-unsubstituted n-glucosamine residues before and after incubation with microbial enzyme. The two types of experiments conform in showing a strict requirement for a specific structure of the carbohydrate backbone; (1→4)-β-D-glucuronosyl-(1→4)-α-D-N-acetylglucosaminyl]-n sequences (as in the heparin precursor, PS-NAc) are deacetylated whereas (1→4)-β-β-D-glucuronosyl-(1→3)-β-D-N-acetylglucosaminyl]-l sequences (hyaluronic acid) or (1→4)-β-D-galactosyl-(1→3)-β-D-N-acetylgalactosaminyl]-l (chondroitin) sequences are not. The presence of ester sulfate groups in the substrate molecule (N-desulfated and N-acetylated [14C]PS-N/O-PSO3-) would appear to be compatible with enzyme activity.

These conclusions were corroborated in a third type of experiment in which unlabeled polysaccharides and polysaccharide derivatives were incubated with the enzyme together with the labeled substrate [14C]PS-N[3H]Ac (Table III). Of the various potentially competitive substrates tested only those structurally related to heparin were able to significantly inhibit the release of [3H]acetate. The N-unsubstituted heparin-related polysaccharides were less efficient inhibitors than were either the N-sulfated or the N-acetylated analogs.

### Discussion

N-Deacetylases acting on polysaccharides have to our knowledge been found only in bacterial and viral systems (18, 20). In mammalian tissues, enzymatic deacetylation of N-acetylglucosamine 6-phosphate and of noncarbohydrate materials such as N-acetylhistamine and certain histones (21, 22) have been demonstrated. Although the substrates in these reactions are highly different several of the enzymes appear to be stimulated by Mn2+ ions and are thus similar in this regard to the N-deacetylase involved in heparin biosynthesis. These observations suggest a role for Mn2+ ions in the catalytic mechanism of N-deacetylating enzymes.

When mouse mastocytoma microsomal fraction is incubated with UDP-glucuronic acid and UDP-N-acetylgalactosamine, two polysaccharide species, the fully N-acetylated PS-NAc and the partially N-deacetylated PS-NH2+, are formed (3, 5). Addition of 3'-phosphoadenylnucleotide (PAPS) to a microsomal fraction containing such preformed, nonsulfated polysaccharides results in rapid conversion of PS-NH2+ into the sulfated species, PS-NSO3- and PS-N/O-PSO3-, the latter species being equivalent to the final biosynthetic product, i.e. heparin (3). While the interconversion of polymeric intermediates has been tacitly assumed to involve also PS-NAc, as a precursor of PS-NH2+, such a relationship has previously not been established. The demonstration of an enzyme in the microsomal fraction that converts exogenous PS-NAc into a product that is similar to PS-NH2+ therefore confirms the postulated pathway of heparin biosynthesis, and, furthermore, indicates that this enzyme, an N-acetylgalactosaminyl N-deacetylase, has an essential role in the overall biosynthetic process. With PS-NAc as an exogenous substrate N-acetyl groups were released in an apparently random fashion, whereas the free amino groups formed seemed to decrease the susceptibility of the remaining acetyl groups to the enzyme. However, it should be observed that this process probably differs from the N-deacetylation reaction occurring in vivo. In the presence of 3'-phosphoadenylnucleotide the free amino groups are substituted with sulfate groups, and these have a stimulatory effect on N-deacetylation.2 Under such conditions, the N-deacetylase and the N-sulfotransferase thus act in a concerted manner that is likely to affect the course of the deacetylation process.

Recent studies on the substrate specificities of the polymer-modifying enzymes operating in heparin biosynthesis have shown that the final modification reactions, uronosyl C5-epimerization and O-sulfation, both occur preferentially or exclusively in the vicinity of previously incorporated N-sulfate groups.3 Since N-deacetylation of heparin precursor molecules is not only the initial polymer-modification reaction, but also a prerequisite step to N-sulfation, it obviously represents potentially one of the prime targets for regulation. The level of N-deacetylation activity and its regulation should thus be an important factor in determining whether a given precursor polymer will ultimately be modified extensively to a high N- and O-sulfated, d-glucuronic acid-rich polymer, i.e. heparin, or whether it will remain at a lower level of modification, as a largely N-acetylated, low sulfated, d-glucuronic acid-rich species, and consequently, be classified as a heparan sulfate. Furthermore, not only will the deacetylase control the overall extent of polymer modification; the distribution of enzyme attacks along the polysaccharide chain should also influence the sequence of variously substituted monosaccharide units in the final biosynthetic product.

In a previous report, the lack of an appropriate nomenclature for the polymeric intermediates of heparin biosynthesis was pointed out (2). It was suggested that the primary biosynthetic product (PS-NAc), composed of d-glucuronic acid and N-acetyl-D-glucosamine, should be termed "N-acetylheparosan." In accord with this proposal the enzyme described in

---

1 N-Deacetylation of hyaluronic acid and chondroitin sulfate by hydrazinolysis (see "Materials and Methods") yields products that are susceptible to degradation by nitrous acid (M. Hook, J. Riesenfeld, and U. Lindahl, unpublished observation). Enzymatic N-deacetylation of [3H]hyaluronic acid or [14C]chondroitin would thus have been detected by the procedure employed.
