Running Title: WD-repeats target myosin heavy chain kinases
**Abbreviations**: BSA (bovine serum albumin), DTT (dithiothreitol), EDTA ([ethylenedinitrilo]tetraacetic acid), GST (glutathione S-transferase), IPTG (isopropyl-β-D-thiogalactoside), MHC (myosin heavy chain), MHCK (myosin heavy chain kinase), MBP (myelin basic protein), PMSF (phenylmethylsulfonyl fluoride), PIC (protease inhibitor cocktail), PKC (protein kinase C), SDS-PAGE (sodium dodecyl sulfate polyacrylamide gel electrophoresis), TLCK (L-1-chloro-3[4-tosylamido]-7-amino-2-heptanone-HCl N-α-tosyl-L-lysine chloromethyl ketone), TPCK (L-1-chloro-3-[4-tosylamido]-4-phenyl-2-butanone tosyl-L-phenylalanine chloromethyl ketone), TBS (Tris-buffered saline).
Summary

Myosin heavy chain kinase A (MHCK A) phosphorylates mapped sites at the carboxyl-terminal tail of Dictyostelium myosin II heavy chain (MHC), driving disassembly of myosin filaments both in vitro and in vivo. MHCK A is organized into three functional domains that include an amino-terminal coiled-coil region, a central kinase catalytic domain unrelated to conventional protein kinases, and a WD-repeat domain at the carboxy-terminus. MHCK B is a homologue of MHCK A that possesses structurally related catalytic and WD-repeat domains. In the current study, we explored the role of the WD-repeat domains in defining the activities of both MHCK A and MHCK B using recombinant bacterially-expressed truncations of these kinases either with or without their WD-repeat domains. We demonstrate that substrate targeting is a conserved function of the WD-repeat domains of both MHCK A and MHCK B and that this targeting is specific for Dictyostelium myosin II filaments. We also show that the mechanism of targeting involves direct binding of the WD-repeat domains to the myosin substrate. To our knowledge, this is the first report of WD-repeat domains physically targeting attached kinase domains to their substrates. The examples presented here may serve as a paradigm for enzyme targeting in other systems.
Introduction

Complex cellular processes such as cytokinesis, cell migration, and receptor capping depend on the ability of myosin II (conventional myosin) to bring about contraction at specific locations within the cell (1). In Dictyostelium, myosin II undergoes a dynamic assembly/disassembly process that permits its specific spatial and temporal localization within the cell (2). In response to extracellular chemoattractants such as cAMP or folic acid, myosin II is recruited from the cytoplasm to the cell cortex in a process that involves myosin II bipolar filament assembly (3-5).

MHC phosphorylation is the major route by which myosin filament assembly is controlled in Dictyostelium. Phosphorylation of mapped sites at threonine residues 1823, 1833, and 2029 of MHC leads to disassembly of filaments both in vitro and in vivo (6-9). The importance of these target sites in controlling myosin filament assembly has been demonstrated from studies showing that conversion of these threonines to aspartic acid residues creates a “pseudophosphorylated” myosin that is unable to assemble into the cytoskeleton. Conversely, myosin over-assembles into the cytoskeleton if these regulatory sites are either removed by truncation of MHC (10) or converted to non-phosphorylatable alanine residues (9).

MHC phosphorylation appears to be regulated in Dictyostelium through the combined activities of at least one MHC phosphatase (11) and a group of MHC kinases (2,12). Dictyostelium MHC Kinase A (MHCK A) was the first of the heavy chain kinases to be purified. Subsequent characterization of purified MHCK A revealed that its catalytic activity can drive myosin filament disassembly in vitro by phosphorylating MHC (13). Cloning and sequence analysis of the MHCK A gene has revealed that the catalytic domain of MHCK A is unrelated to any of the conventional protein kinases. As a result, MHCK A has become the prototype defining a new family of protein kinases (14,15). A structurally related kinase, MHCK B, has been identified and cloned from Dictyostelium via sequence homology to the catalytic domain of MHCK A. While native MHCK B has not yet been purified, a bacterially expressed truncation of MHCK B phosphorylates MHC preferentially at the mapped regulatory sites discussed above (16). Another Dictyostelium homologue of MHCK A, which has been identified by cDNA and genomic sequencing, has been named MHCK C although it has not yet been characterized at the protein level (GenBank Accession # AF079447).

The MHCK A group of kinases in Dictyostelium share a conserved domain structure consisting of the novel kinase catalytic domain and a carboxyl-terminal domain containing seven tandem copies of the WD-repeat motif. The WD-repeat is a conserved amino acid motif that recurs four to sixteen times and is found in a large and heterogeneous family of proteins. The general makeup of the repeating unit, while not absolutely conserved among WD-repeats, begins with a pair of GH residues followed by a variable core of about 36-46 amino acids and ends with the WD residues (17). The crystal structure of the β-subunit
of the heterotrimeric G-protein complex (Gβ) has revealed that its seven WD-repeats fold into a ring-like β-propeller structure consisting of seven “blades” with each blade folded into a four-stranded anti-parallel β-sheet structure (18). While no structural information is available for the WD-repeat domains of MHCK A, B, and C, the conservation of their seven repeats with those of the Gβ subunit indicates that the seven-bladed β-propeller structure is also likely to occur in these Dictyostelium proteins.

Functionally, the WD-repeat class of proteins has been implicated in the regulation of a number of cellular functions such as signal transduction, RNA processing, gene regulation, vesicular traffic, and cytoskeletal assembly; however, no common function or interaction has been attributed to the WD-repeat domain specifically (17). Insight on the function of the WD-repeat domain of MHCK A has been gained from a previous study showing that a Dictyostelium-expressed truncation of MHCK A lacking its WD-repeat domain (MHCK A-ΔWD) was unable to phosphorylate myosin II in vitro and in vivo. In contrast, MHCK A-ΔWD phosphorylated a soluble myosin-based peptide (MH-1) just as well as full-length MHCK A (19).

In the current report, we describe results from experiments exploring the structure/function relationship between the conserved WD-repeat domains of MHCK A and MHCK B and the kinase activity of each enzyme. For these studies, the catalytic domains of MHCK A and MHCK B, either with or without their WD-repeat domains, were expressed in bacteria as recombinant glutathione-S-transferase (GST) fusion proteins and then assayed for kinase activity towards several different substrates, including Dictyostelium myosin II. We found that the WD-repeat domains of both MHCK A and MHCK B stimulate kinase activity towards myosin II substrate but not towards the other substrates tested. These results provide strong support for the hypothesis that MHCK B, like MHCK A, functions physiologically as an MHC kinase. Binding experiments presented here reveal that the mechanism by which the WD-repeats promote kinase activity towards myosin substrate is likely to involve a direct interaction with myosin II. To our knowledge, this represents the first time a WD-repeat domain has been shown to physically target an attached kinase domain to its substrate.
Experimental Procedures

Plasmid Constructs.

All DNA manipulations were carried out using standard methods. For the MHCK A constructs, an intermediate plasmid (pMEX) containing the entire MHCK A DNA coding region was used to generate the inserts for the GST fusion vector. The numbers corresponding to the restriction sites are derived from the MHCK A DNA sequence (GenBank accession number P42527). For the pGST-A-CAT construct, pMEX was digested with HindIII (bp 1493) and BstXI (bp 2529), and the resultant 1036 base pair fragment was treated with Klenow polymerase (New England Biolabs) to yield blunt ends. The pGST-A-CAT construct was completed by ligating the 1036 bp fragment into pGEX-2T (Pharmacia) and then digesting with Smal to generate an in phase fusion with GST. The pGST-A-CATWD construct was made in a similar manner but the fragment was released from pMEX by digesting only with HindIII and then treating the fragment with Klenow polymerase to yield blunt ends. The upstream end is contained within a bacterial polylinker downstream of the native MHCK A termination codon. The 2.0 kb insert fragment was then ligated into pGEX-2T cut with Smal.

MHCK B constructs were made from an intermediate plasmid, pMM3.1, which contains the full-length cDNA-coding region of MHCK B (GenBank accession number P90648). pMM3.1 contains the entire downstream end of MHCK B and has an EcoR1 linker inserted next to codon 13 at the upstream end of the MHCK B coding region. For the pGST-B-CAT construct, a 1.4 kb insert fragment was isolated from pMM3.1 using an internal EcoRV site (nt1391) which lies 3' of the catalytic domain of MHCK B and an XbaI site in the upstream polylinker of pMM3.1. The XbaI site was made blunt by treatment with Klenow polymerase and then ligated into pGEX-2T vector that had been digested with EcoRI and made blunt. This ligation recreated the upstream vector EcoRI site (junction of blunt EcoRI ligated with blunt XbaI). This plasmid insert also contains the EcoR1 site that lies adjacent to codon 13 of the MHCK B coding region. Digestion of this intermediate with EcoR1 was performed to cut at the upstream vector EcoR1 site and at the internal EcoR1 site. Subsequent recircularization yielded pGST-B-CAT which has codon 13 of MHCK B fused directly to the upstream GST domain encoded by the vector and an artificial stop codon following residue 459 of MHCK B. This stop codon lies at a position approximately 110 amino acids downstream of the conserved catalytic domain portion of the native protein. The pGST-B-CATWD construct was prepared in a similar fashion. pMM3.1 was digested with EcoRI, releasing a 2.2 kb restriction fragment that has the entire downstream end of the MHCK B coding region and an upstream EcoR1 site adjacent to codon 13 of MHCK B. This fragment was ligated into pGEX-2T to yield pGST-B-CATWD.

A GST fusion protein containing a 15 kDa segment of the Dictyostelium myosin II heavy chain was expressed in E.coli from the plasmid pGST2029. Construction of pGST2029 involved the subcloning of a segment of myosin II tail centered on the MHCK A target site mapped to position 2029 (7) into the pGEX-
3X (Pharmacia) expression plasmid. An 80 amino acid region of the myosin II gene spanning residues 1985 to 2064 was amplified using primers that introduced upstream and downstream EcoRI restriction sites. The PCR product was cut with EcoRI and ligated into pGEX-3X vector digested with EcoRI. The resulting plasmid, pGST2029, was then electroporated into *E.coli* cells (strain BL21-DE3, Novagen) for expression.

**Protein Purification.**

The four GST fusion proteins were purified in a similar manner. A 100 ml culture of *E. coli* (BL21-DE3 strain, Novagen) containing each plasmid was grown overnight in a 37°C shaker incubator. This culture was then used to inoculate (1/50 dilution) 1 to 2 liters of LB (Gibco-BRL) containing ampicillin (50 µg/ml, Boehringer-Mannheim) and the cultures were grown at 37°C to log phase (*A$_{600}$* of 0.6 to 1.0). At this time, cultures were cooled to 25°C and then 1 mM IPTG was added to induce fusion protein synthesis. Induced cultures were incubated for 15 to 20 hours at 25°C on a rotating platform. Cells were then harvested by centrifugation at 6,000xg for 5 minutes and the resulting cell pellet was washed in 25 mM Tris buffer (pH 7.5) and then centrifuged again. The cell pellet was resuspended (5 ml per gram pellet weight) with Buffer A (25 mM Tris pH 7.5, 150 mM KCl, 5 mM DTT, and 1 mM EDTA) containing 175 µg/ml PMSF and 2x concentration of the protease inhibitor mixtures, PIC-I and PIC-II. PIC-I was added from a 1,000 x stock containing 2 mg/ml antipain, 10 KIU/ml aprotinin, 10 mg/ml benzamidine, 1 mg/ml leupeptin, 5 mg/ml peffabloc, and 10 mg/ml TLCK in ddH$_2$O. PIC II (1,000 x) contains 1 mg/ml chymostatin, 1 mg/ml pepstatin, and 5 mg/ml TPCK in ethanol.

All subsequent purification steps were performed at 4°C. Lysozyme (100 µg/ml, Sigma) was added to the resuspended cells. The cell mixture was sonicated in an ice water bath and the resulting lysate was spun at 150,000 x g for 15 minutes to remove insoluble material. The cleared lysate was incubated with glutathione-sepharose beads (Pharmacia) for 3 to 5 hours at 4°C. The beads were then washed several times with buffer A to remove unbound material. For samples used in autophosphorylation experiments, a dephosphorylation step was added by incubating (12 hours at 4°C) bead-bound fusion protein in Buffer A containing 50 units of calf intestinal alkaline phosphatase (CIAP, Boehringer-Mannheim). After incubation, CIAP was removed by washing the beads with Buffer A. Bound fusion protein was then eluted with buffer A containing 30 mM glutathione (Sigma) and the eluate was dialyzed against 12.5 mM Tris pH 7.5 in 40% glycerol. Aliquots were frozen on dry ice and then stored at -80°C until used in assays.

The GST-2029 fusion protein was prepared as described above but with the following modifications. A 1 liter culture of *E.coli* (BL21-DE3) cells containing the pGST2029 plasmid was grown to log phase at 37°C and then expression of the GST-2029 fusion protein was induced with 1 mM IPTG. The culture was grown for 3 hours at 37°C and then cells were harvested by centrifugation. The cell pellet was resuspended in TBS containing 175 µg/ml PMSF and 1 mg/ml pepstatin. The cell slurry was frozen in a dry-ice/methanol
bath and stored overnight in a -80°C freezer. The following components were added after thawing the cells for purification of GST-2029: 1 mM DTT, 1 mM benzamidine, 100 µg/ml TPCK, 50 µg/ml TLCK, 1 mM EDTA, and 100 µg/ml lysozyme. After a 10-minute incubation on ice, Sarkosyl was added to 1.5% and the cells were sonicated until fully lysed. Triton-X-100 (2%) was added prior to centrifuging the sonicate and the cleared supernatant was incubated with glutathione sepharose beads for 45 minutes at 4°C. Unbound material was removed by washing the beads with buffer containing 20 mM Tris pH 7.5, 50 mM NaCl, and 1 mM EDTA. Fusion protein was eluted from the washed beads using 10 mM glutathione in wash buffer. The peak of eluted protein was determined by Bradford assay (Pierce) and pooled fractions were treated with aquacide (CalBiochem) to concentrate. The resulting concentrate was dialyzed into 10 mM TES pH 7.0, 1 mM EDTA, and 1 mM DTT and then stored in aliquots at -80°C until used.

Myosin was purified by a modification of the method of Aguado-Velasco et al. (20), as has been described (11). Briefly, an initial actomyosin precipitate was subjected to several assembly/disassembly cycles followed by a final gel filtration step to remove residual actin.

**Phosphorylation Assays.**

All kinase assays were performed at 25°C in 10 mM TES pH 7.0, 2 mM MgCl$_2$, 0.5 mM DTT, and 0.5 mM [γ-$^32$P]ATP (250-400 Ci/mol), using recombinant kinases at 20 to 80 nM, as noted for each experiment. The substrates used in this study were MH-1 peptide, GST-2029 (38 kDa), and myosin (243 kDa). The peptide substrate MH-1 (RKKFGESEKTKTEFL-amide) has been described previously (21) and corresponds to the mapped MHCK A target site in the myosin II tail at residue 2029 (underlined in peptide above). For kinetic analysis of kinase activity, each of the substrates was used over a range of concentrations as noted for each experiment. For determination of MHC phosphorylation stoichiometry, myosin II was included in the reaction mix at a concentration of 0.42 µM. For myosin substrate specificity experiments, rabbit skeletal muscle myosin II (Sigma) and chicken gizzard myosin II (Sigma) were dialyzed against Dictyostelium myosin II storage buffer (5 mM Tris pH 7.0 buffer containing 20% sucrose) prior to their addition to kinase reaction mixes.

Unless indicated otherwise, each kinase was allowed to auto-phosphorylate for 10 minutes at 25°C before starting the kinase reaction with the addition of substrate. Kinase reactions containing MH-1 peptide substrate were terminated by blotting a fraction of the reaction mixture onto P-81 filter paper (Whatman) and then processing the filter for scintillation counting (22). For reactions in which the substrate was either GST-2029 or myosin II, the reaction was stopped by adding an equal volume of 2 x SDS-PAGE sample buffer at each time point, boiling for 2 minutes, and then performing SDS-PAGE on the samples. The resulting gels were stained with Coomassie blue and protein bands of interest were excised for scintillation counting to quantify phosphate incorporation. Analysis of fusion protein autophosphorylation was performed by incubating the kinase constructs (200 nM) in the kinase reaction
described above and then blotting a fraction of the reaction mix to P-81 filter paper as described for the peptide assay.

**Protein Concentration Determination.**

Purified kinase constructs were subjected to SDS-PAGE with a series of known amounts of BSA on the same gel. After Coomassie Blue staining, the protein bands were quantified by scanning densitometry and the concentration of each purified fusion protein was determined by comparing the densitometry values for the purified kinases with those of the BSA standards in the same gel.

**Myosin II Co-Sedimentation Assays.**

Centrifuge tubes used throughout these experiments were pre-treated with Sigmacote (Sigma) and 3% BSA in 25 mM Tris pH 7.5. Kinase fusion proteins used in co-sedimentation assays were pre-cleared by centrifugation at 95,000 x g for 10 minutes in a Beckman Ti Tabletop Ultracentrifuge in a TLA 100.3 rotor. The resulting supernatants were transferred to clean centrifuge tubes and then mixed with the other binding assay components to give 40 µl reaction mixes containing 0.3 µM kinase fusion protein, 1.0 µM *Dictyostelium* myosin II, 0.1% BSA, 2.5 mM TES pH 7.0, 40 mM KCl, 2 mM MgCl₂, and 5% sucrose. Under these conditions, greater than 80% of the myosin II is in filaments (25). After incubation for 10 minutes at 4°C, the binding reactions were centrifuged for 10 minutes at 95,000 x g and equal volumes of pellet and supernatant fractions were resolved by SDS-PAGE. The myosin II and BSA were visualized by Coomassie blue staining of gels. The distribution of kinase fusion proteins in pellets and supernatants was determined from Western blots probed with anti-GST antibody (Upstate Biotechnology, NY). The relative amounts of kinase fusion protein in the pellet and supernatant fractions were quantified by densitometric analysis of the developed Western blots.
Results

Construction of MHCK A and MHCK B Truncations Expressed and Purified as GST Fusion Proteins.

In earlier studies, domain truncations of MHCK A were generated for expression in Dictyostelium cells. Biochemical analysis of the purified constructs revealed that the WD-repeat domain of MHCK A was necessary for efficient phosphorylation of intact myosin II, but not for phosphorylation of a myosin-based peptide (MH-1) substrate (19). In the current study, we explored further the role of WD-repeat domains in defining the kinase activities of both MHCK A and its recently identified homologue, MHCK B. For this study, truncated forms of both kinases were constructed, expressed, and purified as GST fusion proteins either lacking or containing their WD-repeat domains (Figure 1). The GST-A-CAT fusion protein construct contains the minimal region of MHCK A that is necessary for basal kinase catalytic activity (23). The GST-A-CATWD fusion protein encompasses this segment and the carboxyl terminal WD-repeat domain of MHCK A. In contrast to MHCK A, the catalytic properties of MHCK B have not been studied thoroughly and nothing is known of the WD-repeat domain contribution to MHCK B kinase activity. While a fine level mapping of the catalytic domain of MHCK B has not been performed, comparison to the MHCK A sequence suggests that the region of MHCK B necessary for basal kinase catalytic activity is probably contained within residues 100-340 (16). The GST-B-CAT fusion protein used in this study encompasses this region and the GST-B-CATWD construct includes this region as well as the more distal WD-repeat domain of native MHCK B. All of the constructs described above were expressed in E.coli and purified to near homogeneity (Figure 1).

The Role of the WD-Repeat Domain in Defining MHCK A Catalytic Activity Towards Various Substrates.

The GST-A-CAT and GST-A-CATWD constructs were assayed for kinase activity towards intact myosin II. Initial experiments determining the time course of MHC phosphorylation by each of the GST fusion proteins revealed that only the GST-A-CATWD construct phosphorylated myosin efficiently (Figure 2A). The GST-A-CAT construct exhibited kinase activity that was barely detectable above background levels. Similar results were obtained when GST-A-CAT and GST-A-CATWD activities were analyzed over a range of myosin II concentrations (Figure 2B). While kinetic parameters for MHC phosphorylation could not be determined due to the insolubility of myosin II substrate at higher concentrations (≥ 2 μM), these results clearly show that the presence of the WD-repeat domain is required for efficient phosphorylation of myosin II by MHCK A.

The recombinant GST-A-CAT and GST-A-CATWD fusion proteins were tested next for kinase activity towards the MH-1 peptide. MH-1 is a previously described (21) 16 residue peptide corresponding to the mapped MHCK A target site at residue 2029 of MHC. Both GST-A-CAT and GST-A-CATWD
phosphorylated MH-1 substrate efficiently (Figure 2C and Table I) and exhibited specific activities within an order of magnitude to those reported previously for both native MHCK A (13) and recombinant MHCK A catalytic domain expressed as a 6xhistidine-tagged fusion protein (Table I) (23). Our results showing a lack of difference between the activities of GST-A-CAT and GST-A-CATWD towards MH-1 demonstrates that the presence or absence of the WD-repeat domain does not affect the basic catalytic activity of MHCK A. Moreover, these results, together with the myosin II phosphorylation results described above, demonstrate unequivocally that the recombinant WD-repeat domain is necessary and sufficient to stimulate MHCK A catalytic activity towards Dictyostelium myosin II.

The lack of WD-repeat targeting to the MH-1 peptide suggests that a larger structural target, perhaps filamentous myosin II, is needed for the WD-repeat domain stimulatory effect. To characterize further the specificity and possible structural requirements for the WD-repeat domain effect on kinase activity, the GST-A-CAT and GST-A-CATWD fusion proteins were tested for kinase activity towards a novel substrate, GST-2029. This substrate contains a GST domain fused to a 15 kDa segment of the Dictyostelium myosin II tail which is centered on the mapped MHCK A phosphorylation site at residue 2029 of MHC. GST-2029 lacks regions of the myosin tail necessary for bipolar filament assembly (24); however, previous studies of Dictyostelium myosin II, along with structure prediction analysis of the GST-2029 sequence, indicate that this construct, unlike the MH-1 peptide, is likely to form a coiled-coil dimer. Assays using the GST-A-CAT and GST-A-CATWD constructs revealed that both fusion proteins phosphorylated GST-2029 equally well with no significant enhancement of activity by the WD-repeat domain (Figure 2D). As with myosin II substrate, kinetic values could not be determined for GST-2029 since this substrate was insoluble at concentrations required to reach $V_{\text{MAX}}$ conditions. Our results showing kinase activity towards MH-1 peptide and GST-2029 is unaffected by the presence of the WD-repeat domain indicate that the enhancement of kinase activity by the WD-repeat domain is specific to myosin II.

Characterization of MHCK B Catalytic Activity and Identification of the Role of the WD-Repeat Domain.

To assess whether the WD-repeat domain of MHCK B confers similar targeting properties towards myosin II, the recombinant GST-B-CAT and GST-B-CATWD fusion proteins were assayed for kinase activity towards myosin II filaments, MH-1 peptide, and GST-2029. As was observed for the MHCK A-derived fusion proteins, the GST-B-CAT and GST-B-CATWD constructs displayed nearly equivalent levels of activity towards MH-1 (Figures 3C, Table I) and GST-2029 (Figure 3D) substrates. However, when myosin II was used as the substrate, the WD-repeat containing construct (GST-B-CATWD) displayed significantly higher activity towards native myosin II filaments, relative to the GST-B-CAT fusion protein (Figure 3A and 3B). Although the stimulatory effect of the WD-repeat domain from MHCK B was not as dramatic as with MHCK A,
several independent preparations of the MHCK B constructs have consistently shown WD-repeat-dependent stimulation of kinase activity towards myosin II. The lower level of stimulation by the WD-repeat domain of GST-B-CATWD may be due to improper folding of this domain when expressed in *E. coli* or may reflect a fundamentally lower stimulatory effect of this domain relative to the corresponding domain of MHCKA. Further studies with purified native MHCK B may be needed to resolve this point.

Comparison with the activities of the MHCK A constructs reveals that the MHCK B-derived fusion proteins exhibited lower rates of kinase activity towards GST-2029 and myosin II. However, when a non-physiological substrate such as MBP was included in the reaction, the MHCK B fusion proteins showed equivalent or higher rates of substrate phosphorylation (Table II); indicating that the inherent catalytic activities of these constructs is not lower than those of the MHCK A fusion proteins. Moreover, while neither the MHCK A nor the MHCK B fusion proteins phosphorylated non-physiological myosins from skeletal or smooth muscle sources very well, the MHCK B fusion proteins displayed significantly higher activity towards these substrates than did the MHCK A fusion proteins (Table II).

**Role of the WD-Repeat Domain in the Autophosphorylation of MHCK A and MHCK B.**

The fusion proteins of both MHCK A and MHCK B were also assessed for the ability to autophosphorylate. Previous studies have shown that autophosphorylation is a major mechanism regulating native MHCK A, resulting in a 50-fold increase in kinase activity (21). In the current study, fusion protein constructs derived from MHCK A consistently autophosphorylated to levels of 1-2 moles P_i/mole kinase (Figure 4A). The level of autophosphorylation does not change if the WD-repeat domain of MHCK A is absent. In comparison, the MHCK B-derived fusion proteins autophosphorylated to a level of 15-20 moles P_i/mole kinase (Figure 4B), with some preparation-to-preparation variability in autophosphorylation stoichiometry. For both the MHCK A and MHCK B-derived fusion proteins, the presence or absence of the WD-repeat domain does not significantly affect autophosphorylation rate or stoichiometry.

**Studies Exploring the Mechanism of WD-Repeat-Mediated Enhancement of Myosin Heavy Chain Kinase Activities.**

The results presented thus far demonstrate that both MHCK A and MHCK B require their WD-repeat domains to phosphorylate myosin II efficiently but do not depend on the presence of their WD-repeat domains for basic catalytic activity towards other substrates. However, it is not clear if the WD-repeat domain interacts with myosin II to physically target the kinase catalytic domain to its substrate or if an interaction between the WD-repeat domain and myosin II results in stimulation of the inherent catalytic activity of the kinase. As a means of testing the latter possibility, the GST-A-CAT and GST-A-CATWD constructs were assayed for kinase activity towards MH-1 peptide in the presence and absence of myosin II. Under these conditions, neither kinase construct was
stimulated to phosphorylate MH-1 peptide above normal levels; thus indicating that the kinase catalytic activity is not affected by an interaction between the WD-repeat and myosin II (Figure 5). These findings further support a role for the WD-repeat domain in physically targeting the kinase specifically to myosin substrate.

To explore the possibility that WD-repeat targeting of MHCK A and MHCK B involves a direct interaction with myosin, we assayed all four of the fusion proteins for co-sedimentation with myosin filaments. Results from these assays revealed that up to 40% of the WD-repeat containing constructs of both MHCK A and MHCK B bound directly to myosin II filaments under the conditions used in the co-sedimentation assay (Figure 6A, B, and C). In contrast, the GST-A-CAT and GST-B-CAT fusion proteins, both of which lack WD-repeat domains, exhibited significantly less co-sedimentation with myosin II filaments. Sedimentation of GST alone was not detectable in the presence or absence of myosin (data not shown). A GST fusion protein containing only the WD-repeat domain of MHCK A was also tested, but high basal sedimentation due to aggregation made this construct unsuitable for these assays (data not shown). In order to determine if the catalytic domain contributes to myosin II binding, we assayed GST-A-CATWD and GST-B-CATWD for co-sedimentation with myosin II filaments in the presence of MH-1 peptide. Under these conditions, an interaction between the catalytic domain and myosin II should be inhibited by peptide binding to the substrate-binding site. Our results demonstrate that the presence of MH-1 peptide at either 100 µM and 400 µM has no detectable effect on MHCK A or MHCK B binding to myosin II filaments and thus suggest that the interaction of the kinases with myosin II is mediated mainly through their WD-repeat domains with little contribution from the catalytic domains. These results, showing that both MHCK A and MHCK B bind to myosin filaments in a manner that requires the presence of a WD-repeat domain, indicate that the mechanism by which the WD-repeat domain promotes myosin phosphorylation involves physically targeting the kinases to myosin substrate.
Discussion

In the experiments presented here we have shown that the structurally related WD-repeat domains of MHCK A and MHCK B share a conserved mechanism for targeting MHC kinase catalytic activity by binding directly to myosin substrate. This WD-domain mediated binding facilitates the phosphorylation of MHC. For MHCK A, the functional consequence of this phosphorylation is to promote myosin II filament disassembly and ultimately to inhibit myosin II-mediated contraction in cells (9,19,25). Further studies are needed to characterize the physiological roles of MHCK B and to determine if MHCK B phosphorylation of MHC is restricted to the same or different sites phosphorylated by MHCK A.

Using recombinant, bacterially-expressed GST fusion proteins of MHCK A and its homologue MHCK B, we have shown that both kinases are targeted by their WD-repeat domains to phosphorylate myosin II substrate specifically. Assays of these constructs revealed that full kinase activity towards native myosin substrate is achieved only with MHCK A and MHCK B fusion protein constructs containing their corresponding WD-repeat domains. MHCK A and MHCK B fusion proteins lacking their WD-repeat domains exhibit reduced ability to phosphorylate myosin II. In contrast, activities of the kinases towards soluble substrates such as the MH-1 peptide or GST-2029 are not affected by the presence or absence of their WD-repeat domains. This demonstrates that the basal kinase catalytic activities of both MHCK A and MHCK B are independent of their WD-repeat domains. It is noteworthy that target recognition appears to involve an extended structural component since phosphorylation of GST-2029, a myosin-based substrate that is predicted to fold into a coiled-coil conformation but which lacks the region necessary for filament formation, is not stimulated by the presence of the WD-repeat domain.

The mechanism by which the WD-repeat domain targets the kinase to myosin II does not involve stimulation of the inherent activity of the catalytic domain since the ability of GST-A-CATWD to phosphorylate MH-1 peptide is not enhanced in the presence of myosin II (Figure 5). Kinetic analysis of kinase activity over a range of myosin concentrations from 0.25 µM to 1.5 µM revealed no saturation of the reaction rate (Figures 2B and 3B). Solubility limitations preclude assays at fully physiological myosin II concentrations (~5µM, ref. 19); however, the lack of saturation or of an apparent $V_{\text{MAX}}$ in these tests suggests that the WD-repeat domains confer an elevated affinity of the kinases for myosin but do not lead to formation of a rigid substrate-enzyme complex. Further studies will be needed to see if there are cellular mechanisms that may dynamically regulate this affinity in vivo, and whether substrate binding requires a fully assembled bipolar myosin filament or simply an extended region of the monomeric myosin tail.

Using myosin II co-sedimentation assays we have determined that the conserved WD-repeat domains of both MHCK A and MHCK B target MHC kinase catalytic activity by binding directly to myosin II substrate. To our knowledge, this represents the first report of a WD-repeat domain physically
targeting an attached kinase domain to its substrate. While further examples are needed, the fact that the WD-repeat domains of both MHCK A and MHCK B are substrate targeting domains may indicate that β-propeller domains present in other protein kinases play similar roles in substrate targeting. Potential candidates for testing this possibility include the *Dictyostelium* protein MHCK C, which possesses catalytic and WD-repeat domains related to those of MHCK A, and a recently identified bacterial protein from *Thermomonospora curvata* which is predicted to contain a conventional serine/threonine kinase domain coupled to a WD-repeat containing region (26). Recently, the WD-repeat domain of a receptor for activated protein kinase C (Rack1) has been shown to bind the cytoplasmic region of the integrin β-subunit and has been proposed to recruit activated protein kinase C (PKC) to integrins (27). Thus, the WD-repeat domain of Rack1, while not covalently attached to PKC, may play a direct role in targeting PKC activity to a substrate.

MHCK A, B, and C have a conserved domain structure that includes a catalytic domain unrelated to conventional protein kinases, with a WD repeat domain that lies carboxyl-terminal to the catalytic domain. Members of the emerging family of eEF-2 kinases, present throughout the animal kingdom (15,28,29), contain a catalytic domain highly related to that of MHCK A, B and C, but do not have detectable WD repeat motifs. However, these enzymes all contain a carboxyl-terminal domain of roughly similar size to the WD-repeat domains observed in MHCK A, B, and C. Recent work from Pavur and colleagues has revealed that the carboxyl-terminal segment of eEF-2 kinases also acts as a targeting domain towards the eEF-2 substrate (30). Moreover, these researchers identified a degenerate repeat motif present in the eEF-2 kinase targeting domain. This 36 amino acid repeat is intriguingly similar in size to the WD-repeat motif (~40 amino acids) but is not detectably related to WD-repeats at the primary sequence level.

The actin-fragmin kinase of *Physarum* may also display a related mode of targeting. This enzyme contains a highly divergent kinase catalytic domain with a fold related to conventional protein kinases (31). Carboxyl-terminal to the catalytic domain, this enzyme contains a domain with a predicted β-propeller structure of the Kelch class (32). Notably, removal of the β-propeller domain was reported to cause a significant decrease in enzyme activity when assayed against the native actin-fragmin substrate (other substrates were not tested). We suggest that in this enzyme as well, the β-propeller domain may be serving a substrate targeting role.

Results from our studies of WD-repeat domain targeting of MHC kinase activity provide strong evidence that MHCK B is a physiologically relevant myosin heavy chain kinase. While the isolated catalytic domain of MHCK B has been shown to preferentially phosphorylate the mapped MHCK A target sites on MHC (16), we have found that the initial rate of activity of the MHCK B constructs towards myosin II and myosin-like substrates (MH-1 and GST-2029) is significantly lower than that observed for the MHCK A fusion proteins (Table I). This does not appear to be due to inherently lower kinase activity since the MHCK B fusion proteins phosphorylate MBP, a non-physiological substrate, at a
higher rate than do the MHCK A constructs. In comparison with MHCK A, the MHCK B fusion protein shows greater substrate promiscuity, exhibiting relatively higher initial rates of kinase activity towards skeletal muscle and smooth muscle myosin substrates. While further studies of the activity and substrate specificity of native MHCK B will be important, the results presented here raise the possibility that myosin II may not be the only cellular substrate for MHCK B.

In summary, we have shown that the catalytic activities of MHCK A and MHCK B are targeted specifically to myosin II by a mechanism that involves direct binding via their associated WD-repeat domains. We suggest that this targeting mechanism may be conserved among an array of identified protein kinases that have β-propeller domains adjacent to their catalytic domains. While MHCK A and B fusion proteins share the property of binding to myosin filaments via their WD-repeat domains, other aspects of their kinase activity clearly differ, suggesting different cellular roles for these enzymes.

Initial rate values of kinase activity were calculated from a one minute kinase assay of activity towards the substrates listed above.
Figure Legends

**Figure 1. Recombinant MHCK Fusion Protein Constructs.** (A) Schematic diagrams of full-length MHCK A and the bacterially-expressed truncations of MHCK A used in this study. Numbering indicates positions of included amino acids from MHCK A (GenBank accession # P42527). At left is an SDS-PAGE gel (Coomassie Blue-stained) of purified GST-A-CAT and GST-A-CATWD (2 µg each). (B) Schematic diagrams of full-length MHCK B and its bacterially-expressed truncations used in this study. Numbering corresponds to included amino acids from MHCK B (GenBank accession # P90648). Coomassie Blue-stained SDS-PAGE gel at left was loaded with 2 µg of purified GST-B-CAT and GST-B-CATWD each.

**Figure 2. Phosphorylation of myosin II heavy chain, MH-1 peptide, and GST-2029 using MHCK A-derived fusion proteins either containing or lacking the WD-repeat domain.** (A) The stoichiometry of *Dictyostelium* myosin II (0.42 µM) phosphorylation by GST-A-CAT and GST-A-CATWD (both at 20 nM final concentration) was assessed over time by subjecting kinase reactions to SDS-PAGE, Coomassie blue staining, and then scintillation counting of the excised MHC band (see Experimental Procedures). Plotted points represent the mean values from two separate experiments. (B) GST-A-CAT and GST-A-CATWD constructs were assayed for kinase activity over a range of myosin II concentrations using the method described for the myosin stoichiometry experiment above. (C) The MHCK A fusion proteins were assessed for kinase activity over a range of MH-1 peptide concentrations using the filter binding method described in Experimental Procedures. The inset is a Lineweaver-Burk plot of the values obtained from this assay. (D) GST-A-CAT and GST-A-CATWD activities were assessed over a range of GST-2029 concentrations by excising GST-2029 bands from Coomassie-stained SDS-PAGE gels followed by scintillation counting of those bands. For all of the plots in this figure, GST-A-CAT is represented by closed symbols (●) and open symbols (○) represent the activity of the GST-A-CATWD fusion protein. The GST-A-CAT and GST-A-CATWD constructs used in all of these experiments were pre-autophosphorylated for 10 min prior to their addition to the reaction mix. For substrate concentration range experiments (Graphs B, C, and D), both GST-A-CAT and GST-A-CATWD were included in the reaction mixes at a final concentration of 40 nM and incubated with substrate for 1 minute at 25º C. For graphs (B), (C), and (D), the plotted values represent the mean activity determined from at least 4 independent experiments. The vertical bars indicate the standard error of each mean.

**Figure 3. Phosphorylation of MH-1 peptide, MBP, and myosin II using MHCK B-derived fusion proteins either containing or lacking the WD-repeat domain.** (A) The stoichiometry of myosin II phosphorylation (0.42 µM) by GST-
B-CAT and GST-B-CATWD (20 nM each) was assessed via SDS-PAGE and scintillation counting of the Coomassie blue stained MHC band. (B) The MHCK B fusion proteins (80 nM) each were incubated (4 min at 25°C) with a range of myosin II concentrations and specific activity measurements were made as described for (A). (C) The activities of GST-B-CAT and GST-B-CATWD towards MH-1 peptide were determined by incubating (2 min at 25°C) the fusion proteins (40 nM) with a range of peptide substrate concentrations. The filter-binding assay (see Experimental Procedures) was used to determine phosphate incorporation. The inset graph is a Lineweaver-Burk plot of the values obtained from this assay. (D) The activities of GST-B-CAT and GST-B-CATWD (40 nM each) were assessed over a range of GST-2029 concentrations (4 min incubation at 25°C) by subjecting reaction mixes to SDS-PAGE and then excising the GST-2029 band. The amount of phosphate incorporation was determined by scintillation counting of excised bands. Activity of the GST-B-CAT construct is represented by the closed symbols (•) and open symbols (ο) represent activity of the GST-B-CATWD fusion protein. The GST-B-CAT and GST-B-CATWD constructs used in all of these experiments were pre-autophosphorylated for 10 min prior to their addition to the reaction mix. For graphs (B), (C), and (D), the plotted values represent the mean activity determined from at least 4 independent experiments. The vertical bars indicate the standard error of each mean.

Figure 4. Autophosphorylation of MHCK A and MHCK B-derived fusion proteins. Autophosphorylation reactions were performed at 200 nM of each kinase construct and the level of autophosphorylation was determined with a filter binding assay as described in Experimental Procedures. (A) Autophosphorylation of GST-A-CAT (•) and GST-A-CATWD (ο) versus time. Inset represents the same data plotted to a smaller scale. (B) Autophosphorylation of GST-B-CAT (•) and GST-B-CATWD (ο) versus time.

Figure 5. Phosphorylation of MH-1 peptide by GST-A-CAT and GST-A-CATWD in the presence and absence of myosin II. The MHCK A fusion proteins (40 nM) each were incubated (4 min at 25°C) with 50 µM MH-1 substrate in the presence (gray bars) or absence (black bars) of 0.5 µM myosin II. Specific activity towards MH-1 peptide was measured using the filter binding method described in Experimental Procedures. Values obtained from control reactions containing only kinase and myosin II were subtracted from experimental values to control for MHC phosphorylation in these reactions. The GST-A-CAT and GST-A-CATWD constructs were pre-autophosphorylated for 10 min prior to their addition to the reaction mix. The bars represent the mean activity from 3 independent experiments with the error lines representing the standard error of each mean.

Figure 6. Co-sedimentation assays of MHCK A and MHCK B-derived fusion proteins with myosin II filaments. Kinase fusion proteins (0.3 µM) were
incubated with myosin filaments (1.0 µM) as described in Experimental Procedures. Reaction mixes were centrifuged and equal volumes of the resulting pellets (P) and supernatants (S) were subjected to SDS-PAGE. Myosin and BSA were visualized by Coomassie blue staining of the gel and the kinase fusion proteins were identified by Western blotting with anti-GST antibody. (A) Representative Western blot (top) and Coomassie-stained gel (bottom) from a myosin co-sedimentation assay of GST-A-CAT and GST-A-CATWD. (B) Representative Western blot (top) and Coomassie-stained gel (bottom) from a myosin co-sedimentation assay of GST-B-CAT and GST-B-CATWD. (C) Bar graph of kinase construct binding to myosin II. The bar values represent the means from three separate experiments performed in duplicate and the error bars represent the standard error of each mean. (D) Bar graph of GST-A-CATWD and GST-B-CATWD co-sedimentation with myosin II in the presence and absence of MH-1 peptide. Co-sedimentation results were quantified by densitometric analysis of Western blots and the amount of fusion protein in the pellet fraction was divided by that in both the pellet and supernatant to yield the values indicated by the graph bars.
