Intracellular phospholipase A₂ (PLA₂) plays an important role in regulating oxylipin biosynthesis in mammals, but the molecular and biochemical nature of intracellular PLA₂ is not well understood in plants. Arabidopsis thaliana gene At1g61850 (AtPLAI) encodes a 140 kD protein that is most similar to mammalian calcium independent PLA₂, and additionally contains leucine-rich repeats and Armadillo repeats. AtPLAI hydrolyzes phospholipids at both the sn-1 and sn-2 positions, but prefers galactolipids to phospholipids as substrates. Profiling of lipid species altered in response to the necrotrophic fungus Botrytis cinerea revealed decreases in the levels of phosphatidylglycerol and digalactosyldiacylglycerol, suggesting that hydrolysis of plastidic polar lipids might provide precursors for pathogen-induced JA production. Disruption of AtPLAI by T-DNA insertion reduced the basal level of jasmonic acid, but did not impede pathogen-induced production of jasmonic acid, free linolenic acid, or hydrolysis of plastidic lipids. Still, AtPLAI-deficient plants exhibited more damage than wild type plants after B. cinerea infection, and pretreatment of plants with methyl jasmonate alleviated pathogen damage to the mutant plants. The study shows that AtPLAI is an acyl hydrolase, rather than a specific phospholipase A. AtPLAI is involved in basal jasmonic acid production and Arabidopsis resistance to the necrotrophic fungus Botrytis cinerea.

As a non-specific necrotrophic pathogen, Botrytis cinerea infects more than 200 plant species (1). It obtains nutrients from dead host cells and attacks plants by producing cell wall-degrading enzymes, toxic reactive oxygen species (ROSs1), and host nonselective toxins, resulting in repression of host defense gene transcription, maceration of plant tissue, or host cell death (2). Plants use both pre-existing and induced defense strategies to cope with pathogen infection (3). One important defense response is the production of oxylipins, which include a variety of oxygenated fatty acid-derived compounds (4–6). The best known oxylipins are jasmonic acid (JA) and its derivatives, collectively called jasmonates (JAs). JAs induce changes in host defense responses, including increased expression of proteinase inhibitors, phenylalanine ammonia lyase, chalcone synthase, and proline-rich cell-wall proteins (7–11). JA plays a positive role in plant response to necrotrophic pathogen infection (12).

Great progress has been made in the understanding of oxylipin biosynthesis and its biological functions (4–6, 13). Linolenic acid, the most abundant fatty acid in green plant tissues, is the precursor for JA formation. However, the initial step that makes linolenic acid available for JA biosynthesis is not well understood. Since it is a component of membrane lipids, attached via an ester linkage, linolenic acid is presumed to be released from complex lipids by a lipolytic activity, such as by phospholipase A (PLA), analogous to that in animal systems (4–5, 8). In Arabidopsis, a link between PL₄ and JA biosynthesis was reported, but the identified PLA₄ is involved in anther dehiscence and pollen maturation, rather than in defense-induced JA formation in vegetative tissues (14). The discovery of arabidopside and other complex plastidic lipids containing oxylipins has led to speculation that a lipoxygenase may act...
on intact plastidic membrane lipids and that intact oxylipin-containing polar complex lipids may be the substrate for a hydrolytic enzyme (15–17). In any case, studies using different plant systems have implicated a role of PLA-like activity in mediating defense responses. Early studies showed that free fatty acids and lysophosphatidylethanolamine could modulate 1,3-β-glucanase activity and callose deposition in suspension-cultured soybean cells (18). The production of free fatty acids and lysophospholipids is induced in various elicitations, such as cell wall extracts from fungus Phytophthora parasitica var. nicotianae on tobacco cells, harpin and fungal Verticillium dahliae extracts on suspension-cultured soybean cells, oligosaccharide elicitors on tomato leaves, fungal elicitors on cultured cells of California poppy, by wounding, and by systemin (19–24). However, the gene and biochemical identities of the lipolytic enzymes involved in JA production in defense response are not defined.

In mammalian cells, intracellular PLA2 plays a critical role in the release of arachidonic acid for the synthesis of eicosanoid oxylipins (25–26). Intracellular PLA2 consists of two major types: Ca²⁺-dependent PLA2 (cPLA2) and Ca²⁺-independent PLA2 (iPLA2). In comparison, Arabidopsis has no homolog to cPLA2, but plant patatins share sequence similarities with the catalytic region of iPLA2 (27). The term patatins refers to a group of closely-related vacuolar storage proteins in potato tubers; these proteins possess non-specific acyl hydrolase activity, releasing fatty acid groups from several types of lipids, including phospholipids and galactolipids (28). Patatin-like proteins are present in other plant species and have been implicated in defense responses. For example, the expression of patatin-like genes was induced in tobacco cells infected with tobacco mosaic virus, bacterium Erwinia carotovora, fungus Botrytis cinerea, or treated with a cell death-inducing protein elicitin, β-megaspermin (29–30). In addition, acyl-hydrolyzing activity increased before cell death and before the accumulation of 12-oxophytodienoic acid (OPDA) and JA, suggesting that patatin-like proteins mediate the production of JA and defense responses in tobacco (29–30). In Arabidopsis, the expression of the patatin-like gene At2g26560 (AtPLAI) was shown to be induced in response to various abiotic and biotic stresses (31). However, suppression of the gene increased plant susceptibility to pathogen, implying that the patatin-like activity may facilitate, rather than suppress, pathogen infection (32). Arabidopsis has nine genes with sequences closely related to patatin (32–33). But there has been no direct evidence for a positive role for patatin-like enzymes in the production of JA and in plant response to pathogens.

Another gene in Arabidopsis, designated AtPLAI (At1g61850)(33), encodes a protein with a patatin catalytic domain, but an overall sequence more similar to mammalian iPLA2 than to other Arabidopsis patatin-like proteins. While the other nine patatin-like genes encode proteins with 382 to 526 amino acid residues, AtPLAI encodes a protein about 800 amino acid residues larger than those patatins. In addition, it contains multiple leucine-rich repeats (LRR) at its N-terminus. These distinctive features raise intriguing questions about the enzymatic identity and cellular functions of AtPLAI. Here, we show that AtPLAI is an acyl hydrolase that uses both phospholipids and galactolipids as substrates, that it is involved in basal jasmonic acid production, and that it promotes Arabidopsis resistance to the necrotrophic fungus Botrytis cinerea.

**EXPERIMENTAL PROCEDURES**

**Plant Materials -** Arabidopsis thaliana plants (ecotype Wassilewskija) were grown in growth chambers under a day/night regimen of 23/18ºC and 10/14 h photoperiod under white light of 150 µmol m⁻² s⁻¹. The T-DNA insertion mutants at gene AtPLAI (patatin-like acyl hydrolase 1) at the locus At1g61850 were isolated by screening T-DNA insertion lines according to the protocol of the Arabidopsis Gene Knockout Research Facility at the University of Wisconsin (34). The two mutants (Atplai-1 and Atplai-2) have T-DNA inserted at the 2nd exon and the 16th exon of the gene, respectively. The sites of T-DNA insertion were confirmed by sequencing, and the homozygous plants were used in the study.

**Genetic Complementation of Mutant Plants -** A 7.8-kb genomic fragment of DNA containing the coding region of AtPLAI (At1g61850) and 1.42 kb 5’ and 0.55 kb 3’ untranslated regions was amplified by PCR. The PCR product was cloned into the AscI site of pEC291 binary vector. The resulting vector was introduced into the C58C1
strain of *Agrobacterium tumefaciens*, and the *AtplaI*-1 mutant plants were transformed as described (35). The measurement of JA in the complemented plants and the pathogen test with *B. cinerea* were performed as described below.

*Treatment of Plants with Pathogen, JA and SA* - Fungus strain *Botrytis cinerea* was used for inoculation of 5-week-old soil-grown plants. Fungal spores were prepared and quantified as described (36). For inoculation, each leaf was pricked 3 times using a 23 gauge needle, and each wound was covered immediately with a 10 µl drop of a suspension of 10⁵ conidial spores per ml in potato dextrose broth medium. Inoculated plants were incubated at 18°C under dim light at 100% relative humidity in propagator flats covered with a clear polystyrene lid for the time periods indicated. For chemical treatments, 5-week-old soil-grown plants were sprayed with a solution of 0.01% ethanol and 0.1% Triton X-100 in water containing either 0.5 mM salicylic acid (pH 6.5) or 50 µM methyl jasmonate (pH 6.8) 48 h prior to inoculation with *B. cinerea*. Control plants were sprayed with a solution containing only 0.01% ethanol and 0.1% Triton X-100.

*cDNA Cloning and Expression of Recombinant Protein in E. coli* - The cDNA library CD4-16 was obtained from the *Arabidopsis* Biological Resource Center (ABRC) in Ohio State University. The full length cDNA of *AtPLAI* gene was obtained with PCR using the cDNA library as a template and primers of forward 5′-CGCGTCGACTGATGTCTTCTACATGTTC-3′ and reverse 5′-CTTGCGGCCGCGTCTTTCTATACATTAGG-3′. The cDNA was cloned into a pGEMT-vector (Promega) and both strands were sequenced. The coding sequence of *AtPLAI* (3798 bp) was amplified with PCR and cloned into the SmaI and SalI sites of the pGEM-4T-1 vector (Amersham) after the GST coding sequence. The sequence of the GST-fusion construct was verified before it was introduced into *E. coli* strain BL-21(DE3). The cells were grown to an OD₆₀₀ of 0.7 and induced with 0.4 mM IPTG for 12 h at 22°C. The purification of the GST fusion protein was performed as described previously (37) and the protein concentration was determined with the Bradford method (38). The purity of the protein was analyzed by 8% SDS-polyacrylamide gel electrophoresis (PAGE), followed by Coomassie blue staining.
Galactolipid Preparation and Enzyme Assays—MDGD and DGDG were purified from Arabidopsis leaves. Lipid was extracted from young Arabidopsis leaves and separated as described (39). For enzyme assays, the solvent of the lipid extract was evaporated under a nitrogen stream, and MGDG or DGDG was emulsified in water containing 0.05% Triton X-100 by sonication. The enzyme assay mixture contained 50 mM Tris-HCl, pH 8.0, 10 mM CaCl₂, 0.05% Triton X-100, 100 µM galactolipid substrates, and 10 µg enzyme protein in a final volume of 200 µl. The reaction was incubated for 1 h at 30ºC and then stopped by adding 700 µl chloroform/methanol (2:1, v/v) and 200 µl of 2 M KCl. Lipids from the chloroform phase were separated by TLC in chloroform/methanol/ammonium hydroxide/water (65:39:4:4, v/v/v/v). Lipid spots were visualized by exposure to iodine vapor. Free fatty acid (FFA) spots were scraped and methylated by adding 1.5 ml of 1.5% sulfuric acid in methanol containing 0.01% butylated hydroxytoluene and triheptadecanoin (C17:0) as an internal standard and heating at 90ºC for 60 min. Methylated fatty acids were extracted by successively adding 1.0 ml of H₂O and 1.0 ml hexane. Fatty acid methyl esters were quantified using an Agilent 6890 gas chromatograph with flame ionization detection and an HP-INNOWax column (30 m length x 0.25 mm inner diameter, 0.25 µm film thickness; Agilent). Also, the non-enzymatic product formation was subtracted from the enzyme-produced products.

Preparation of Oxylipin-Rich Total Lipid from Wounded Plants and Enzyme Assay—Leaves of four-week old plants were wounded mechanically with a forceps and total lipids were extracted 45 min after wounding as described (39). The lipids were emulsified in distilled water containing 0.05% Triton X-100 by sonication and used as a substrate. 30 µg of the lipids (1 µg/µl) and 5 µg purified AtPLAI were added to each reaction in a final volume of 200 µl. The other assay conditions for acyl-hydrolyzing activities were as described above. Control reactions contained the same amount of lipids and empty-vector bacterial proteins and were subjected to the same purification process as those reactions containing AtPLAI. After the reaction the lipids were extracted and the organic phase was analyzed by mass spectrometry.

Real-Time Quantitative RT-PCR—RNA was isolated from liquid nitrogen-frozen plant leaves using a cetyltrimethylammonium bromide extraction method as described previously (40). Ten micrograms of RNA was reverse-transcribed using the iScript™ cDNA Synthesis Kit (Bio-Rad) containing a blend of oligo (dT) and random hexamer primers. Quantitative RT-PCR was performed on 50 ng cDNA with the iQ™ SYBR Green Supermix (Bio-Rad). Amplification of Arabidopsis polyubiquitin gene (UBQ10) transcripts derived from gene At4g05320 were used as reference. The gene specific primer pairs used for the PCR are (from 5′ to 3′): AtPLAI (At1g61850): forward ACACCGAACAAGTGGAC TGGGAGATAG, reverse TGATCTGAGCTT TCGATGAGAGGCA; lipoygenase2 (LOX2, At3g45140): forward AGAGCTGGA TCTGTTGTTGTTAAG, reverse AAACAGCGACATCATCAG; allene oxide synthase (AOS, At5g42650): forward TGGTGCCGAGTTGT GTTGATTG, reverse ATAAACGGAGCTTCC TAAACCGCAG; allene oxide cyclase 1 (AOC1, At3g25760): forward CTTAAGCGCGGAGA AAGAAGTTAAGT, reverse TATATC AATACACGAGATCGAGAAG; hydroperoxide lyase (HPL, At4g15440): forwardCGTCGAACAAACGTTGCTGCAGCTA, reverse TAAATCGGCAACGAGCAAGGAAGG; 12-oxo-phytodienoic acid (OPDA) reductase (OPR3, At2g06050): forward CGG ATTTGGTTTCGC GGGTGCTAACAAGGAAAGGAC; 12-oxophytodienoic acid (OPDA) reductase (OPR3, At2g06050): forward CGG ATTTGGTTTCGC GGGTGCTAACAAGGAAAGGAC; 12-oxophytodienoic acid (OPDA) reductase (OPR3, At2g06050): forward CGG ATTTGGTTTCGC GGGTGCTAACAAGGAAAGGAC; 12-oxophytodienoic acid (OPDA) reductase (OPR3, At2g06050): forward CGG ATTTGGTTTCGC GGGTGCTAACAAGGAAAGGAC; 12-oxophytodienoic acid (OPDA) reductase (OPR3, At2g06050): forward CGG ATTTGGTTTCGC GGGTGCTAACAAGGAAAGGAC; 12-oxophytodienoic acid (OPDA) reductase (OPR3, At2g06050): forward CGG ATTTGGTTTCGC GGGTGCTAACAAGGAAAGGAC.
Analysis of JA and Free Linolenic Acid - Approximately 50 to 100 mg of fresh Arabidopsis tissues were sealed in 1.5 mL snap-cap vials. After being frozen in liquid nitrogen, the leaves were ground to powder, and 500 µL of 1-propanol/H₂O/concentrated HCl (2:1:0.002, v/v/v) with internal standards was added, followed by agitation for 30 min at 4°C. Dichloromethane (1 mL) was added, followed by agitation for another 30 min and then centrifugation at 13,000 × g for 1 min. The bottom layer was used for JA and linolenic acid analysis. Dihydrojasmonic acid (H₂JA) and heptadecanoic acid (C17:0) were used as internal standards for JA and linolenic acid quantification, respectively.

Plant extracts were firstly separated by HPLC, equipped with a reversed-phase column (C18 Gemini 5µ, 150 × 2.00 mm, Phenomenex, CA, USA), using a binary solvent system composed of water with 0.1% formic acid and methanol with 0.1% formic acid as a mobile phase at a flow rate of 0.3 mL/min and a gradient of linearly increasing methanol content from 30% to 100% at 30 min. A hybrid triple quadrupole/linear ion trap mass spectrometer (API 4000, Applied Biosystems, Foster City, CA) outfitted with an electrospray ion source, was used in multiple reaction monitoring (MRM) mode. JA, H₂JA, linolenic acid and C17:0 eluted at 12.44, 13.74, 20.7 and 22.01 min respectively.

JA, linolenic acid, H₂JA and C17:0 can easily lose one proton from the carboxylic group and become negatively charged precursors, so they were analyzed in negative scan mode. An appropriate precursor-to-product ion transition that represents a major fragmentation path and is unique for each phytohormone was identified, and MS/MS conditions, including collision energy, collision cell exit potential, declustering potential, and entrance potential were optimized to produce maximal signal. The unique precursor ions and product ions were identified using authentic compounds. Precursor ions ([M−H]^−) of JA, linolenic acid, H₂JA and C17:0 are m/z 209, m/z 277, m/z 211, and m/z 269, respectively, which were monitored by Q1. After collision induced dissociation in Q2 under the optimized conditions, the precursor ions of JA, linolenic acid, H₂JA and C17:0 (m/z ratio of 209, 277, 211, and 269) give rise to a major fragmentation ion of m/z 59, 259, 59, and 251 for JA, linolenic acid, H₂JA and C17:0 in the MS/MS spectra of authentic compounds. Therefore, the diagnostic product ions, m/z ratio of 59, 259, 59, and 251 were selected to be monitored by Q3, and the precursor-to-product ion transitions of 209→59, 277→259, 211→59 and 269→251 are used to quantify JA and linolenic acid. The peak area of the main diagnostic product ion was used for quantification.

Lipid Profiling - The processes of lipid extraction, lipid analysis, and lipid quantification were performed as described (41-42). Briefly, after inoculation of Botrytis cinerea, leaf samples were harvested for lipid analysis at indicated time intervals. Lipid samples were analyzed on an electrospray ionization triple quadrupole mass spectrometer (API 4000, Applied Biosystems, Foster City, CA). The molecular species of phospholipids and galactolipids were quantified in comparison to the two internal standards using a correction curve determined between standards (41-43). Five replicates of each treatment for each phenotype were processed and analyzed. Paired values were subjected to the Student t-test to determine the statistical significance.

Multiple acyl precursor and head group neutral ion scanning was used to quantify the levels of major oxylipin containing galactolipid molecular species (17). Briefly, scans of the head group and oxylipin acyl anions were performed in the oxylipin-containing galactolipid mass range (m/z 750-1050). Head group neutral loss scans of 179 and 341 (to identify the [M + NH₄]^+ ions of MGDG and DGDG, respectively) were used to quantify the total amount of the oxylipin-containing species of each nominal mass. By integrating the specific precursor oxylipin acyl chain scans with the neutral loss head group scan, the individual molecular species were quantified. For quantification purposes, internal standards of 16:0/18:0 MGDG (2.01nmol), 18:0/18:0 MGDG (0.39 nmol), 16:0/18:0 DGDG (0.49nmol) and 18:0/18:0 DGDG (0.71nmol) were used.

For analysis of AtPLAI hydrolysis in vitro using the mixture of leaf lipids, total lipids were prepared from Arabidopsis leaves as described (39). Solvent was evaporated from the lipids in chloroform under a nitrogen stream, and the lipids were emulsified in distilled water containing 0.05% Triton X-100 by sonication. Acyl-hydrolyzing activities were assayed as described above. Thirty µl of lipid mixture (approximately 1 µg/µl) were used as substrate and 10 µg purified AtPLAI was added to the mixture in a final volume of 200 µl. Control reactions contained the
same amount of lipids and empty-vector bacterial proteins that were subjected to the same purification process as AtPLAI. After the reaction, the resulting lipids were extracted and the organic phase was analyzed by the triple quadrupole mass spectrometry as described above. The differences in lipid content between the control and AtPLAI reactions were divided by the amount of enzyme to calculate the specific activity.

RESULTS

AtPLAI Hydrolyzes Phospholipids and Galactolipids - A full length cDNA of AtPLAI has a complete open reading frame for a protein of 1257 amino acid residues, with a predicted pl of 5.55 and molecular weight of 139279. The coding sequence agrees with that of the annotated AtPLAI gene with 17 exons and 16 introns, a total exon length of 3798 bp, and an intron length of 2111 bp (Fig. 1A). The sequence of AtPLAI is most similar to intracellular calcium-independent PLA2 gamma (iPLA2γ) in humans and rats, but it also contains unique domain structures (Fig. 1B, C). AtPLAI contains one patatin domain between residues 456-702 and two other identifiable domains: four leucine-rich repeats (LRR) from residues 134-156, 157-179, 180-202, and 203-225; and three repeats of Armadillo (Arm) between residues 269-310, 355-393, and 394-435 (Fig. 1B). The last Arm repeat is about 20 amino acid residues upstream of the patatin domain. The Arm repeat is an approximately 40 amino acid tandemly repeated motif first identified in the Drosophila melanogaster segment polarity gene armadillo (44). The amino acid sequence of AtPLAI is 33% identical and 51% similar to human iPLA2γ. AtPLAI is more closely related to a family of proteins including iPLA2 from mammals, nematode, fruitfly, yeast, and bacteria, than to the group of nine patatin-like proteins in Arabidopsis (Fig. 1C).

AtPLAI contains the conserved serine hydrodase motif GXXG at residues 486-490, and a conserved Asp residue at 681. These serine and aspartic acid residues constitute a catalytic dyad essential for the acyl hydrolase activity of this family of lipases (27, 45). To determine whether AtPLAI encodes an active enzyme, AtPLAI was fused to a glutathione-S-transferase (GST) and expressed in E. coli. A protein of 165 kDa corresponding to the predicted size of the GST–AtPLAI protein was purified to apparent homogeneity (Fig. 2A) and was assayed for its ability to hydrolyze various phospholipids. Fluorescent phospholipids, phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidyglycerol (PG), phosphatidic acid (PA), and phosphatidylserine (PS), were used as substrates, and the formation of free fatty acids and lysophospholipids was quantified. Both fluorescent free fatty acids and lysophospholipids were generated by the enzyme (Fig. 2B). Because the fluorescent label [12-(7-nitro-2,1,3-benzoxadiazol-4-yl)amino]-dodecanoyl (NBD)] was at sn-2 position, the detection of both fluorescent lysophospholipids and fluorescent free fatty acid indicates that the enzyme can release fatty acids at both sn-1 and sn-2 positions.

To verify the hydrolytic activity at sn-1 and sn-2 positions, radioactive 1-stearoyl-2-(1-[14C]arachidonoyl)-phosphatidylinositol (PI) was used. Consistent with results from the fluorescent lipid assays, both radioactive free fatty acid and lysoPI were generated (Fig. 2C). The amount of [14C] lysoPI formed was five-fold higher than that of [14C] fatty acid, suggesting that the enzyme prefers hydrolysis of PI at the sn-1 to sn-2 position. The relative amount of NBD-fatty acids vs NBD-lysophospholipids indicates that the enzyme preferred to release the fatty acid at the sn-1 position as compared to the sn-2 position when PC, PE, or PG was the substrate but favored the sn-2 position when PA or PS was the substrate (Fig. 2B). The enzyme also hydrolyzed galactolipids, monogalactosyldiacylglycerol (MGDG) and digalactosyldiacylglycerol (DGDG) (Fig. 2D). The activity of AtPLAI toward galactolipids was actually much higher than that of all the phospholipids tested (Fig. 2B-D).

To determine the lipid selectivity, total lipids extracted from plant leaves were used as substrates for the enzyme, and the resulting decrease in phospholipids and galactolipids was analyzed with electrospray ionization triple quadrupole mass spectrometry. The lipids that AtPLAI hydrolyzed most are MGDG, DGDG, and PG (Fig. 2F), which are predominantly localized in chloroplasts. By comparison, AtPLAI displayed much lower activity toward PC or PE, the two most common extraplastidic phospholipids in leaves. Taken together, these results indicate that AtPLAI is an acyl hydrolase preferring galactolipids, rather than strictly an A-type phospholipase.
To investigate if AtPLAI hydrolyzed oxygenated galactolipids, an oxylipin-rich lipid mixture prepared from wounded Arabidopsis leaves was used as substrates. The major OPDA-containing galactolipid species in the substrate were arabidopside species, A (OPDA/dnOPDA MGDG), B (OPDA/OPDA MGDG), C (OPDA/dnOPDA DGDG), and D (OPDA/OPDA DGDG) (17), and their amounts (means ± SD) were 0.092 ± 0.033, 0.093 ± 0.01, 0.035 ± 0.014, and 0.493 ± 0.066 nmoles per reaction, respectively. AtPLAI hydrolyzed both oxylipin- and non-oxylipin-containing galactolipids (Fig. 3). However, the percentage of oxylipin-DGDG and MGDG hydrolyzed by the enzyme was approximately two to three times higher than that of non-oxylipin-DGDG and MGDG (Fig. 3B). These results indicate that AtPLAI can use diverse lipid species including arabidopside as substrates, and it displays a preference for arabidopside to non-OPDA-containing MGDG or DGDG.

Abrogation of AtPLAI Increases Susceptibility to B. cinerea - Two T-DNA insertion mutants of AtPLAI were isolated by screening the Wassilewskija (WT) ecotype of Arabidopsis. AtplaI-1 contains a T-DNA insertion at nucleotide 438 from the start codon, corresponding to 14 amino acid residues after the start of the LRR domain (Fig. 1A). AtplaI-2 has the insertion at nucleotide 3288, or 394 amino acid residues after the patatin domain (Fig. 1A). The T-DNA insertions resulted in loss of the expression of AtPLAI as indicated by the absence of the detectable transcript quantified by real-time PCR (Fig. 4A). Both mutant alleles cosegregated with kanamycin resistance and susceptibility in a 3:1 ratio, suggesting that each mutant contains a single T-DNA insertion in the genome. The mutant Atplatl-I was complemented by introducing the genomic DNA of AtPLAI with its own promoter.

The response of the two T-DNA insertion mutants to B. cinerea was compared to WT plants. Both WT and mutant leaves developed necrosis at the site of inoculation. However, the mutant plants showed more susceptibility to B. cinerea, as indicated by increased lesion size, necrosis, and maceration of leaves after fungal infection than WT plants (Fig. 4B, C). WT plants developed only mild symptoms of disease; no clear hypersensitive reaction was observed in the first 2 days after fungal infection, and the lesions on later days were small as compared to those on leaves of the mutant plants (Fig. 5A). The infection with B. cinerea resulted in stunted growth for many of mutant plants; growth retardation occurred in a much smaller fraction of WT plants (Fig. 5C). Compared to WT plants, the mutant plants had fewer new leaves emerging after fungal infection (Fig. 5B) and the new leaves were also smaller (Fig. 4B). When the genomic AtPLAI gene fragment was introduced into the mutant AtplaI-1, the transformed plants behaved like wild type, displaying less susceptibility to the fungal infection than the mutants (Fig. 4C). Results from the genetic complementation show that the defect in the mutant plants is caused by the lack of AtPLAI. Collectively, the above results show that disruption of AtPLAI renders Arabidopsis more susceptible to B. cinerea.

Knockout of AtPLAI Decreases the Basal JA Level -To gain insight as to how the defect in AtPLAI compromises the defense response, we tested the hypothesis that ablation of the acyl hydrolase AtPLAI might compromises JA production. Because the two knockout lines responded similarly to the pathogen, most of the following comparative analyses were performed only on WT and AtplaI-1 to reduce the number of samples to be analyzed. Without fungal infection, the basal level of JA in both mutant leaves was significantly lower than that of WT leaves with about 50% less in AtplaI-1 (Fig. 6A). The basal level of JA in the complemented AtplaI-I plants was restored to that in WT (Fig. 6A), confirming that the decreased level of JA was due to the loss of AtPLAI.

To further determine the effect of the AtPLAI mutations on JA production, the expression of several genes involved in oxylipin synthesis and response in WT and mutant was compared by quantitative real-time PCR. Without infection, the expression levels of lipoxigenases 2 and 3 (LOX2 and LOX3), JA carboxyl methyltransferase (MjT), and a 12-oxo-phytodienoic acid reductase (OPR3) were approximately 3-fold higher in WT than in mutant plants (Fig. 6B). The level of a vegetative storage protein (VSP2), a JA-responsive gene, was also higher in WT than in the mutant plants. The attenuated expression of genes involved in oxylipin response is consistent with the decreased level of JA in the mutant plants. On the other hand, the levels of hydroperoxide lyase (HPL) and allene oxide synthase (AOS) were similar between the
mutant and WT plants while allene oxide cyclases 1 and 2 (AOC1, AOC2) appeared higher in the mutant than in WT plants.

**Loss of AtPLAI Does Not Impede Pathogen-Induced JA Production** - When plants were infected with *B. cinerea*, both WT and the mutants exhibited biphasic increases in JA (Fig. 7A). The first increase occurred at 1 hr after inoculation, and the second increase was at 24 h after inoculation. The level of JA at the second peak in WT was approximately 40 times higher than the earlier one (Fig. 7A). The increase at 1 h after inoculation was caused, in part, by wounding that was caused by 3 pricks with a 23 gauge needle used for inoculation. In control plants that were pricked, but not inoculated with *B. cinerea*, JA also increased at 1 h (Fig. 7B). However, unlike pathogen-infected plants, no second peak was observed in control WT or mutant plants (Fig. 7B). Thus, the second, major peak of increase in JA resulted from *B. cinerea* infection. The *AtPLAI* mutant plants displayed wound- and pathogen-induced increase in JA, at a magnitude and time course similar to that of WT plants (Fig. 7A). After fungal infection, the genes involved in oxylipin synthesis, such as LOX2, AOS, OPR3, and AOC2 displayed a similar pattern of induction in both WT and mutants (data not shown).

The level of free linolenic acid before and after fungal infection was measured to determine whether ablation of *AtPLAI* affected the formation of free linolenic acid, a potential substrate for JA synthesis. Without inoculation, the basal level of free linolenic acid in WT was more than 50% higher than that in *Atplai-1* (Fig. 7C). While it remained lower in the mutants than in WT in the earlier hours after inoculation, the levels of free linolenic acid became higher in the mutant than WT at 24 h after infection. The rise in the level of free linolenic acid coincided with the large increase in JA in both WT and mutant plants (Fig. 7A, C). The higher levels of linolenic acid at later times in the mutants as compared to WT could be due to increased lipid hydrolysis (Figs. 8, 9) related to the greater tissue damage by fungal infection in the mutant plant (Figs. 3, 4).

**Plastidic lipids PG and DGDG Are Decreased Earlier than PC and PE after *B. cinerea* Infection** - To investigate the lipid changes after *B. cinerea* infection, we quantitatively profiled polar glycerolipid species in WT and *AtPLAI*-deficient leaves following *B. cinerea* inoculation. Approximately 140 phospholipid and galactolipid species were analyzed, which included the major membrane lipid classes, PC, PE, PI, MGDG, and DGDG, and minor classes, PS, PA, lysoPC, lysoPE, and lysoPG, as well as minor acyl species within each head group class. This lipid profiling analysis is capable of detecting small changes in lipid species, as demonstrated recently by adding small, known amounts of specific lipid species an Arabidopsis lipid extract (46). WT and *Atplai-1* leaves contained similar amounts of polar glycerolipids, measured as either nmol/mg of dry weight (Fig. 8A) or mol% of total lipids analyzed (data not shown).

After WT and *Atplai-1* leaves were inoculated with *B. cinerea*, no significant changes in phospholipids or galactolipids were detected in 0, 1, 3, 6, or 12 h post infection (Fig. 8A and data not shown). At 22 h post *B. cinerea* inoculation, there was no significant decrease in other phospholipids analyzed, except that PG decreased significantly in both WT and the mutant (Fig. 8A). In both genotypes, the PG level in *B. cinerea* infected leaves was about 15% lower than that of control leaves that were pricked but inoculated with mock solution. The decrease came primarily from the predominant species 34:4 PG (Fig. 8B) that is the 18:3-16:1 acyl species (41). The major galactolipid MGDG displayed no change, but the level of DGDG decreased in both genotypes after the pathogen infection (Fig. 8A). The decrease in DGDG come primarily from linolenic acid-containing species, 34:3 DGDG and 36:6 DGDG (Fig. 8B), which are composed primarily of 18:3-16:0, and 18:3-16:3 acyl groups, respectively (41).

When plants were infected with *B. cinerea* for 2 days or more, *Atplai-1* displayed greater decreases in phospholipids PC and PE and more increases in lysoPC and lysoPE than did WT (Fig. 9). *Atplai-1* exhibited greater decreases in PI and PS than did WT 3 days after inoculation (Fig. 9), indicating that different classes of phospholipids have varied susceptibility to degradation during pathogenesis. There was no difference between WT and *Atplai-1* in changes in MGDG or DGDG (data not shown). This greater increase in phospholipid hydrolysis in *Atplai-1* than in WT plants is correlated to the more severe damage in the mutant, but it is unlikely that this late stage increase in phospholipid hydrolysis is involved in JA biosynthesis because JA accumulation peaked at 24 h after infection (Fig. 7A) and phospholipid
hydrolysis peaked between 48 to 72 h after infection (Fig. 9). The similar results in mutant and wild-type suggest that other acyl-hydrolyzing activities, rather than AtPLAI, contribute to the pathogen-induced membrane lipid loss in disease-damaged tissues.

**Pretreatment of MeJA Restores the AtPLAI Mutant Resistance to WT** - The above results indicate that ablation of AtPLAI results in decreases in basal JA, but not in pathogen-induced lipid hydrolysis or JA production. To test whether the decreased resistance to *B. cinerea* in *AtplaI-1* results from a compromised ability to respond to JA, WT and mutant plants were treated with methyl JA (MeJA) prior to *B. cinerea* inoculation. Without MeJA pretreatment, larger lesions were found on mutant leaves than WT leaves, but after MeJA pretreatment, the lesion size in the mutant plants decreased significantly and became indistinguishable from WT plants (Fig. 10).

The effect of pretreatment with salicylic acid (SA) on the mutant response to *B. cinerea* was also examined. When WT and mutant plants were pretreated with SA, the lesions on leaves of both WT and mutant plants were larger than control plants of each genotype (Fig. 10). The increase in disease susceptibility was relatively more in WT than in the mutant. The SA effect is consistent with the hypothesis that SA suppresses JA-mediated defense, thus resulting in increased plant susceptibility to *B. cinerea*. The ability of the *AtPLAI* mutants to respond to the JA and SA pretreatment suggests that the increased disease susceptibility in *AtPLAI* mutants does not result from compromised ability to respond to JA or SA.

**DISCUSSION**

In *Arabidopsis thaliana*, AtPLAI is most similar to mammalian iPLA₂, and additionally it contains Armadillo and LRR domains at its N-terminus. Arm-repeat proteins function in various animal processes, including intracellular signaling and cytoskeletal regulation (47). In higher plants, some Arm-repeat proteins function in intracellular signaling like their animal counterparts, but functions for most of the Arm-containing proteins are unknown in plants (48). Proteins with LRRs include tyrosine kinase receptors, cell-adhesion molecules, virulence factors, and extracellular matrix-binding glycoproteins (49–50). They are involved in a variety of biological processes, such as signal transduction, cell adhesion, DNA repair, recombination, transcription, RNA processing, disease resistance, apoptosis, and immune response. In particular, the LRR domain has been implicated as a primary pathogen recognition domain for plant resistance genes (51–53). These sequence features raise intriguing questions about the enzymatic identity and cellular function of AtPLAI. Specifically, this study investigated the enzymatic activity of AtPLAI and its role in JA production and defense response.

The results show that AtPLAI is an acyl hydrolase with broad lipid substrate specificity. AtPLAI hydrolyzes phospholipids at the sn-1 and sn-2 positions and also is more active toward galactolipids than phospholipids. Galactolipids, MGDG and DGDG, are present primarily in photosynthetic membranes inside chloroplasts. Using GFP-tagging and transient expression systems in tobacco, AtPLAI has been suggested to be localized in chloroplasts (32). Most cellular linolenic acid is esterified to galactolipids, and some enzymes involved in JA biosynthesis, such as AOS and AOC, are also localized in chloroplasts (4–5). Thus, the substrate preference and localization of AtPLAI in chloroplasts would suggest that AtPLAI affects plant functions via its hydrolysis of plastidic lipids. However, ablation of AtPLAI impedes the accumulation of only basal JA, not accumulation of pathogen-induced JA, nor the pathogen-induced hydrolysis of galactolipids or phospholipids.

The effect of AtPLAI on basal JA formation is confirmed by genetic complementation that restored the basal JA accumulation to the WT level. In addition, the positive role of AtPLAI in the basal JA formation is supported by a decrease in the basal level of free linolenic acid and by reduced expression of the JA-responsive gene *VSP2*, whose level of expression is indicative of endogenous JA levels in plants (54–55). The basal levels of expression in WT and *Atplai-1* of other genes potentially involved in JA biosynthesis are varied. The lower level of gene expression for LOX2, LOX3, OPR, and MJT is consistent with the decreased basal level of JA in the mutants and the notion that JA biosynthesis is mediated by a positive feedback regulatory system (14, 56–58). On the other hand, the expression of AOS and AOCs did not display the same decrease. The lack of a correlation of AOS expression and JA levels has been observed in other Arabidopsis
of acyl hydrolyzing enzymes. The finding that the AtPLAI-deficient plants still produce as much pathogen- or wound-induced JA as WT does seems somewhat counterintuitive. One explanation evokes the functional redundancy as WT does seems somewhat counterintuitive. The results also suggest that another acyl-hydrolyzing activity or activities, rather than the burst of JA production (approximately 4.5 nmol/g fresh weight) after the infection. Second, AtPLAI is able to hydrolyze oxygenated DGDG and MGDG and is actually selective more for arabidopside over regular DGDG and MGDG. Third, oxygenated DGDG and MGDG are produced in leaves in response to stimulation. In addition, the result shows DGDG is more oxygenated than MGDG, which is consistent with the changes in lipid species following infection. The early decrease in lipids comes primarily from linolenic acid-containing species, 34:4PG, 34:3DGDG, and 36:6DGDG. These species are made primarily of 18:3-16:1, 18:3-16:0, and 18:3-16:3 acyl groups, respectively (42, 46). By comparison, the level of the major galactolipid MGDG does not decrease, and significant decreases in phospholipids PC and PE occurred 2 days after infection in WT plants. The increased hydrolysis of PC and PE is consistent with increases in lysoPE and lysoPC which peaked between 48 to 72 h after infection. The greater increase in phospholipid hydrolysis in AtPLAI-deficient plants is correlated with more severe disease damage, rather than the burst of JA production. Thus, such increases in phospholipid hydrolysis are likely to be more related to catabolism than to the initial phase of JA production. The results also suggest that another acyl-hydrolyzing activity or activities, rather than AtPLAI, contributed to the membrane lipid loss in disease-damaged tissues.

Considering the plastidic lipid hydrolysis observed and the substrate preference of ATPLAI, the finding that the AtPLAI-deficient plants still produce as much pathogen- or wound-induced JA as WT does seems somewhat counterintuitive. One explanation evokes the functional redundancy of acyl hydrolyzing enzymes. The Arabidopsis genome contains nine patatin-like genes, and two of them have been shown to encode acyl hydrolase activity. The nine genes are divided into two groups: Group I with five genes (At4g37050, At4g37060, At4g37070, At5g43590, and At2g26560) and Group II with four genes (At2g39220, At3g54950, At4g29800 and At3g63200) (32–33). AtPLAI and Group I proteins have the typical serine hydrolase motif GXSG and a conserved aspartic acid as a catalytic dyad essential for lipid acyl hydrolase activity (24, 42). Two Group I proteins (At4g37070 and At2g26560) have been shown to possess acyl-hydrolyzing activity (32–33, 61), but their role in enhancing JA production is unknown. On contrary, At2g26560 is reported to promote pathogen colonization (33), and At2g26560 does not promote JA formation (X. Pan and X. Wang, unpublished data). In addition, the Group II proteins do not contain the conserved Ser-Asp catalytic dyad; the serine in the GXSXG motif is substituted with a glycine, and the aspartic acid in the dyad is also replaced with a glycine. No protein in Group II has been reported to have acyl hydrolase activity, so it is unclear if the Group II proteins have acyl hydrolase activity. Thus, whether the nine patatin-like proteins contribute to the basal or pathogen-induced JA in the AtPLAI mutant remains to be investigated. Another possibility is that other types of phospholipases may regulate wound- or pathogen-induced JA accumulation. There are other A-types of phospholipases in Arabidopsis (62). In addition, previous studies showed that phospholipase Dα1 promotes wound-induced accumulation of free linolenic acid and JA in A. thaliana (39, 59). The data suggest that production of basal JA and stimulus-induced JA is regulated by two separable processes.

JA is well documented to play a positive role in plant response to necrotrophic pathogen infection (12, 56). As shown by this study and others, JA increases rapidly after elicitation and wounding (10, 63). However, the roles of basal vs pathogen-induced JA on plant defense responses are often not distinguished, and little is known about the role of basal level of JA in defense response. The present results show that the AtPLAI-ablated plants are more susceptible to B. cinerea although the mutants produce a similar amount of pathogen-induced JA. One possible explanation for the uncoupling between the increase in pathogen-induced JA and the decrease in B. cinerea resistance in Atplai-1 is that ablation
of AtPLAI might compromise plant ability to respond to JA. This is unlikely, however, because pretreatment of AtPLAI-deficient mutants with JA restores the mutant ability to resist to the pathogen. In addition, when WT and mutant plants were pretreated with SA, the lesions on leaves of both WT and mutant plants were larger than control plants of each genotype. SA and JA activate distinct sets of genes and defense pathways in Arabidopsis and were reported to have antagonistic interactions in Arabidopsis in response to distinct microbial pathogens (12, 64–65). The SA effect is consistent with the hypothesis that SA suppresses JA-mediated defense, thus resulting in increased plant susceptibility to B. cinerea. These results indicate that AtPLAI-disrupted plants have normal ability to respond to JA and SA.

Taken together, the results demonstrate that AtPLAI is an acyl hydrolase, rather than a specific PLA. We propose to redefine AtPLAI as patatin-like acyl hydrolase. In addition, the study suggests that induced JA alone is not sufficient for defense against B. cinerea, and that the basal level of JA is important in defense response. We propose that the acyl-hydrolyzing activity of AtPLAI is involved in maintaining the homeostatic pool of basal free fatty acids and basal JA that plays a positive role in defense responses.

Leaves from plants complemented with *AtPLAI* resembled the wild type in response to *B. cinerea* infection.

**Fig. 5.** Measurements of damage caused by fungal infection. *A.* Lesion diameters on leaves of plants at 3 days after inoculation with *B. cinerea*. *B.* Number of new leaves that emerged from the plants by 7 days after inoculation. *C.* Percentage of plants with retarded growth after inoculation with *B. cinerea*. Data are means obtained from representative experiments performed with 50 plants per genotype. Values are the means ± SD (n = 50). Statistically significant differences between the wild type and either mutant line are marked with asterisks (P < 0.05, according to Student’s t test).

**Fig. 6.** The basal level of jasmonic acid in plants and the relative expression level of *AtPLAI* and several other genes in the oxylipin pathway in WT and *Atplai-1* plants. *A.* The basal level of jasmonic acid in plants without any treatment. Statistically significant differences between WT and mutant are marked with asterisks (P < 0.05, according to Student’s t test). *B.* The relative level of gene expression in plants without treatment. PLAI, *AtPLAI*; LOX2, lipoxygenase 2; LOX3, lipoxygenase 3; AOS, allene oxide synthase; HPL, hydroperoxide lyase; AOC1, allene oxide cyclase 1; AOC2, allene oxide cyclase 2; MJT, jasmonic acid carboxyl methyltransferase; OPR3, 12-oxo-phytodienoic acid (OPDA) reductase 3; VSP2, vegetative storage protein 2. Their accession numbers in the GenBank database are listed in the Methods. The two insets show the expression of *MJT* and *VSP2* gene in plants since their expression level did not match the scale of other genes in the figure.

**Fig. 7.** Jasmonic acid level in plants of WT and *Atplai-1* in response to *B. cinerea* and wounding. *A.* Change in JA level in WT and *Atplai-1* leaves within 50 h after inoculation with *B. cinerea*. *B.* Change in JA level in WT and *Atplai-1* leaves in response to wounding that was caused by 3 pricks with a 23 gauge needle used for inoculation. *C.* Change in linolenic acid in plants in response to infection by *B. cinerea*. Five-week old plants grown in growth chamber were used for inoculation with fungal pathogen *B. cinerea*. Samples of inoculated
leaves were taken at different time points post inoculation. Levels of JA and linolenic acid in plants were determined using mass spectrometry.

**Fig. 8.** Changes in polar glycerolipids as affected by *B. cinerea* infection. *A.* Polar lipid classes in WT and *AtplaI-1* leaves without and with *B. cinerea* infection for 0 and 22 h. *B.* Amounts of PG and DGDG species in WT and *AtplaI-1* leaves without and with *B. cinerea* infection for 0 and 22 h. WT and mutant plants were grown at the same time and in the same growth chamber. Five-week-old plants were inoculated with *Botrytis cinerea* with three pricks to each leaf. Infection (T) was initiated by placing a 10 µl drop of freshly harvested spore suspension (5 x 10^5 spores/ml) on each prick. Control (C) leaves were pricked three times and covered with water. Values are means ± SD (n=5). The value for the PLDα1-deficient plant is lower than the value for WT plants at *P* < 0.05 according to Student’s *t* test.

**Fig. 9.** Differences in phospholipid levels between WT and *AtplaI-1* leaves during *B. cinerea* infection for 4 days. WT and mutant plants were grown at the same time and in the same growth chamber. Five-week-old plants were inoculated with *Botrytis cinerea* with three pricks to each leaf. Infection was initiated by placing a 10 µl drop of freshly harvested spore suspension (5x 10^5 spores/ml) on each prick. Values are means ± SD (n=5). Significant differences between WT and mutant are marked with asterisks (P < 0.05, according to Student’s *t* test).

**Fig. 10.** Effects of JA and SA treatments prior to inoculation on plant response to *B. cinerea* infection. Lesion diameter in leaves of plants pretreated with 50 µM methyl jasmonate (pre-MJ), 0.5 mM salicylic acid (pre-SA) or distilled water (pre-dH2O) 48 h before inoculation with *B. cinerea* as described in Experimental Procedures. The lesion diameter was measured 3 days after inoculation with the fungus on leaves from 50 inoculated plants per genotype. Statistically significant differences between the WT and mutants pretreated with distilled water (pre-dH2O) and between the WT (pre-dH2O) and SA-treatment to WT, *AtplaI-1*, and *AtplaI-2* (pre-SA) are marked with asterisks (P < 0.05, according to Student’s *t* test).
