Keyword: CD38, FcγR, Phagocytosis, Macrophage, [Ca2+]i

----------------------------------------------------------------------------------------------------------------

Background: Ca2+ signaling in FcγR-mediated phagocytosis is unclear.

Results: We show that FcγR-mediated phagocytosis requires the production of cyclic ADP-ribose by CD38.

Conclusion: CD38 plays a crucial role for Ca2+ signaling in FcγR-mediated phagocytosis.

Significance: This study provides new perspectives in immune defense and can help shed light on developing novel methods or drugs for manipulating bacterial infections.

SUMMARY

Phagocytosis is a crucial event in the immune system that allows cells to engulf and eliminate pathogens. This is mediated through the action of immunoglobulin (IgG)-opsonized microbes acting on Fcγ receptors (FcγR) on macrophages, which results in sustained levels of intracellular Ca2+ through the mobilization of Ca2+ second messengers. It is known that the ADP-ribosyl cyclase is responsible for the rise in Ca2+ levels after FcγR activation. However, it is unclear whether and how CD38 is involved in FcγR-mediated phagocytosis. Here we show that CD38 is recruited to the forming phagosomes during phagocytosis of IgG-opsonized particles and produces cyclic-ADP-ribose which acts on ER Ca2+ stores, thus allowing an increase in FcγR activation-mediated phagocytosis. Ca2+ data shows that pretreatment of J774A.1 macrophages with 8-bromo-cADPR, ryanodine, blebbistatin, and various store-operated Ca2+ inhibitors prevented the long lasting Ca2+ signal, which significantly reduced the number of ingested opsonized particles. Ex vivo data with macrophages extracted from CD38-/- mice also shows a reduced Ca2+ signaling and phagocytic index. Furthermore, a significantly reduced phagocytic index of Mycobacterium bovis BCG was shown in macrophages from CD38-/- mice in vivo. This
study suggests a crucial role of CD38 in FcγR-mediated phagocytosis through its recruitment to the phagosome and mobilization of cADPR-induced intracellular Ca\(^{2+}\) and store-operated extracellular Ca\(^{2+}\) influx.

The catalysis of the substrate NAD\(^+\) to Ca\(^{2+}\) second messenger, cyclic ADP-ribose (cADPR), is made possible through the action of the type II transmembrane glycoprotein CD38 due to its ADP-ribosyl (ADPR) cyclase activity (1, 2). Once production is initiated, cADPR can then act on ryanodine receptors (RyR) located on endoplasmic reticulum/sarcoplasmic reticulum (ER/SR) stores which will ultimately lead to an increase in intracellular Ca\(^{2+}\) levels ([Ca\(^{2+}\)]\(_i\)) via Ca\(^{2+}\) release in many different types of cells (3-5). This rise in [Ca\(^{2+}\)]\(_i\) is responsible for various mechanisms in immune cells, and it has been implicated in chemotaxis (6), cell adhesion (7), and cytokine secretion (8).

CD38 can also generate another Ca\(^{2+}\) signaling messenger nicotinic acid adenine dinucleotide phosphate (NAADP) depending on the cell system (9, 10). Like cADPR, NAADP can be very potent in eliciting a rise in [Ca\(^{2+}\)]\(_i\), by acting on receptors of specific Ca\(^{2+}\) stores that are insensitive to thapsigargin (11-13). It has been suggested that these stores are lysosome-related acidic organelles which can provide a long-lasting [Ca\(^{2+}\)]\(_i\) increase similar to ER stores (14-16).

One of the intriguing aspects of CD38 is what is known as the “topological paradox” where the active site of CD38 is located outside of the cellular membrane (17). This begs to ask the question of how CD38 can catalyze the production of its messengers cADPR and NAADP because the substrates NAD/NADP as well as the targets for cADPR/NAADP are present intracellularly. It has been suggested that connexin 43 hemichannels, a component of the gap junction, mediate cADPR generation in the extracellular space or intracellular vesicles, and its approach to RyR by NAD/cADPR transport (18). It has also been suggested that CD38 is internalized once activated via endocytosis, thus allowing its catalytic site to interact with intracellular substrates (19-21). This internalizing event has been observed in many different cellular responses where cADPR production is shifted from the surface to inside the cell (22, 23). It has been suggested that the internalization mechanism is mediated by non-muscle myosin heavy chain IIA (MHCIIA), where both CD38 and MHCIIA were found to be associated with activated lymphokine-activated killer cells (24). Phagocytosis is the mechanism of internalization used by phagocytes to internalize and degrade microorganisms, cell debris, and various particles (25). We have previously reported the possible role of CD38 in Fcγ receptors (FcγR)-stimulated phagocytosis where extracellular NAD can help regulate this event in the J774A.1 cell line (26). Thus, there is a possibility that CD38 internalization is related to FcγR-mediated phagocytosis but there currently have been no studies on CD38 internalization in FcγR-mediated phagocytosis.

Early studies have shown that the accumulation of [Ca\(^{2+}\)]\(_i\) may even be responsible for conducting phagocytosis by controlling many different phenomenon such as phagosomal maturation (26, 27), cytoskeletal rearrangements (27, 31), and phagosome-lysosome fusion (32). There are many different types of receptors on the surface of macrophages that can initiate phagocytosis, such as complement receptors (33, 34), mannose receptors (35, 36), Sp-A receptors (37), scavenger receptors (38), and subfamilies of FcγR. It has been hypothesized that the binding of immunoglobulin-opsonized pathogens with FcγR on the plasma membrane is a major factor in mediating this Ca\(^{2+}\) response (39). This was first seen when Ca\(^{2+}\) signals were detected during phagocytosis of opsonized targets in a variety of immune cells (40-43).

Within the FcγR family, there are four different classes of FcγRs: FcγRI, FcγRII, FcγRIII and FcγRIV, where macrophages are
known to express all four classes (44, 45). Once initiated, the FcγRs will cluster on the outer membrane of macrophages and commence the phosphorylation of immunoreceptor tyrosine-based activation motifs (ITAMs) by Src family tyrosine kinases. The phosphorylated ITAMs will then gather a variety of signaling enzymes and complexes which will start a signaling cascade that ultimately leads to phagocytosis (46, 47). At this point, Syk and PI3K kinases can be activated. Syk in particular can then phosphorylate phospholipase C (PLC)-γ which then cleaves membrane phospholipid PI(4,5)P₂ into inositol trisphosphate (IP₃) and diacylglycerol (DAG) (46-48), where the former binds to Ca²⁺ channels on the ER that allows Ca²⁺ release into the cytosol (49). Any additional Ca²⁺ signaling that is possibly involved afterwards at this point in macrophage phagocytosis has not yet been explored.

In the present study we show that CD38 is recruited and internalized to the phagosome containing IgG-opsonized particles, and induces cADPR production, thereby resulting in intracellular Ca²⁺ increase and FcγR-stimulated phagocytosis enhancement. In addition, we show that CD38 knockout reduces FcγR-stimulated phagocytosis in murine macrophages and inhibits phagocytosis of Mycobacterium bovis BCG in mice. Our results suggest that CD38 is involved in the host’s defense to bacterial infection.

EXPERIMENTAL PROCEDURES

Materials and reagents. Mouse IgG, 3.0 µm polystyrene latex beads, Bovine Serum Albumin, Triton X-100, thiglycollate medium, 8-Br-cADPR, and Streptavidine-Cy3 conjugate were purchased from Sigma-Aldrich (St. Louis, MO). RPMI 1640 medium, DMEM medium, fetal bovine serum, trypsin, and antibiotics were purchased from HyClone Laboratories, Inc (Logan, UT). Fluo-3 AM was purchased from Invitrogen (Eugene, OR). FITC rat anti-mouse CD38 was purchased from BD Biosciences Pharmingen (San Diego, CA). Target retrieval solution, and antibody diluent were purchased from Dako (Denmark). Xestospongin C, Ryanodine, and Blebbistatin were purchased from Calbiochem (San Diego, CA). Bafilomycin A1, and rabbit polyclonal MYH9 antibody were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). Biotinylation of anti-M. bovis BCG polyclonal antibody was carried out through the technical service by Advanced Biochemicals Inc. (Jeonju, South Korea).

Animals. C57BL/6 mice were purchased from OrientBio (Sungnam, South Korea). CD38 knockout mice were purchased from Jackson Laboratory. Mice were bred and kept in animal housing facilities at Chonbuk National University Medical School under SPF conditions. All experimental animals were used under a protocol approved by the institutional animal care and use committee of the Chonbuk National University Medical School. Standard guidelines for laboratory animal care were followed.

Cell culture. The murine macrophage cell line J774A.1 (obtained from ATCC) and macrophages prepped from wild-type C57BL/6 and CD38-/- mice were maintained at 37°C, 5% CO₂ in RPMI supplemented with 10% heat-inactivated FBS, 100 U/ml penicillin, and 100 µg/ml streptomycin. The cells were passaged weekly and cells older than 15 passages were not used.

IgG-opsonized latex bead preparation. Polystyrene latex beads (3.0 µm) were washed repeatedly with Hank’s balanced salt solution (HBSS) (1.5 mM CaCl₂, 145 mM NaCl, 5 mM KCl, 1 mM MgCl₂, 5 mM D-Glucose, 20 mM HEPES, pH 7.3) and spun down at 1,700 RPM at 4°C for 10 min. After washing, mouse IgG was added at a concentration of 3 mg/ml. The beads were then incubated at 4°C on a rotator for 8 hours to prevent any bead settling and to allow...
proper binding. After incubation, the beads were resuspended and washed repeatedly with cold buffer to remove any unbound IgG and kept on ice for immediate use.

**TRITC IgG-opsonized latex bead preparation.** Soluble IgG was dialyzed with PBS at 4°C for 2 hours. The buffer was then replaced with 100 mM sodium carbonate buffer (10 mM Na₂CO₃, 90 mM NaHCO₃, pH 8.8) and the IgG solution was again dialyzed at 4°C for an additional 2 hours. TRITC was then added to the IgG solution and mixed thoroughly overnight at room temperature. For further purification and to separate any unbound TRITC, the IgG+TRITC solution was passed through a Sephadex G-75 column and was collected. The amount of recovered TRITC-bound IgG was measured with a spectrophotometer at a wavelength of 280 nm. The appropriate amount of TRITC-bound IgG was opsonized to latex beads as mentioned in the above protocol.

**Preparation of polyclonal antibody against M. bovis BCG.** Rabbits were given an initial 1-ml subcutaneous injection of a crude sonically treated incomplete Freund's adjuvant (Sigma-aldrich, MO) mixture. Injections were given at five separate sites. Similarly prepared injections of 1 ml were repeated once after one month. Blood was obtained after one month, and the sera was isolated and designated as anti-BCG.

**Immunohistochemistry.** J774A.1 cells were plated on 24-well plates with coverslips at a density of 2.5 x 10⁵ cells. Phagocytosis was initiated with TRITC-bound IgG-opsonized latex beads for 30 min at 37°C in 5% CO₂ incubator. Cells were then immediately washed repeatedly with HBSS to remove any unbound beads and were fixed with 3.7% paraformaldehyde solution for 1 hour at 4°C. The cells were then washed with PBS to remove excess paraformaldehyde and permeabilized with target retrieval solution according to the manufacturer’s protocol. Cells were then washed with PBS and blocked with a filtered blocking buffer (1% BSA, 0.1% Triton X-100, 0.02% Na₃ in PBS) at 4°C for 1 hour. Primary FITC conjugated rat anti-mouse CD38 antibody or rabbit polyclonal MYH9 antibody were diluted with an antibody diluent (1:200) and were incubated in the wells overnight at 4°C. Wells were then washed repeatedly with TTBS (0.1 M Tris-HCl pH 7.4, 150 mM NaCl, 0.1% Tween-20) with gentle shaking. Fluorochrome labeling to unconjugated antibodies were carried out through the technical service provided by Advanced Biochemicals Inc. (Jeonju, Korea). The stained cells were then exhaustively washed and the coverslips were then removed and mounted on slides. The slides were viewed under a Carl-Zeiss confocal microscope (LSM 510 META, Jena, GmBH) at the Center for University-wide Research Facilities (CBNU, Jeonju, Korea). For three dimensional imaging, confocal Z-stacks (0.98 μm-thick) were sequentially captured. Z-sections were combined into a Z-stack, and XZ-sections/YZ-sections of the Z-stack were reconstructed using the Zeiss LSM Image Browser (Ver 4.2.0.121) to visualize internalized-molecules positioning in the cell.

**Preparation of mouse macrophage.** Briefly, each mouse was injected intraperitoneally with 2 ml of 3% thioglycollate medium. After 5 days, the mice were sacrificed and the thioglycollate-
induced macrophages were extracted via peritoneal lavage with DMEM. The macrophages were centrifuged at 1,500 rpm at 4°C for 3 min and then resuspended at a cell concentration of 2 x 10^6 cells/ml with RPMI. Macrophages were plated in 100 mm culture dish and kept in a 5% CO_2 incubator at 37°C for 2 hours. Non-adherent cells were then washed off with Dulbecco’s Phosphate-Buffered Saline (DPBS) (2.67 mM KCl, 1.47 mM KH_2PO_4, 137.93 mM NaCl, 8.06 mM Na_2HPO_4.7H_2O) and the attached macrophages were kept in RPMI in a 5% CO_2 incubator at 37°C. Isolated macrophages were used within 24 hours.

**Determination of ADPR cyclase Activity.** ADPR cyclase activity was determined fluorometrically using nicotinamide guanine dinucleotide (NGD+) as a substrate (50). Phagocytosis was initiated in 2 x 10^6 cells per microtube at various time points with IgG-opsonized latex beads. The microtube-containing cells were incubated with 200 µM NGD+ (pH 7.2) at 4°C for 30 min. The reaction was then stopped with 10% TCA and the cells were pelleted by centrifugation. Fluorescence of cGDPR produced was determined at excitation/emission wavelengths of 297/410 nm (Hitachi F-2000).

**Phagocytic assay.** J774A.1 cells were plated at a density of 1 x 10^6 cells per well in a 6-well plate overnight. The cells were pre-treated with various nucleotides for 30 min at 37°C in 5% CO_2 incubator. For phagocytosis, the media was removed and replaced with RPMI containing non-opsonized or IgG-opsonized latex beads for 30 min at 37°C in 5% CO_2 incubator. The cells were then washed twice and fixed with 3.7% paraformaldehyde solution. Phagocytosis was assessed by light microscopy. Images were acquired using a Nikon Eclipse TS100. Images were acquired were captured using AVT-ActiveCam Viewer V1.1.0. The phagocytic index was calculated as follows: phagocytic index (PI) = number of latex beads internalized by 100 J774A.1 cells counted in 10 random fields.

**Fluorimetric determination of intracellular Ca^{2+}** concentration. J774A.1 cells or macrophages extracted from wild-type and CD38-/- C57BL/6 mice were washed twice with HBSS. Cells were then incubated with 5 µM fluo-3 AM in HBSS at 37°C for 30 min. The cells were washed three times with HBSS. Changes in fluorescence in the cells were determined at 488 nm excitation/530 nm emission by an air-cooled argon laser system. The emitted fluorescence at 530 nm was collected using a photomultiplier. One image was scanned every 4 s for 10 min using a confocal microscope (Nikon, Japan). For the calculation of [Ca^{2+}], the method of Tsien et al. (51) was used with the following equation: 

\[ [Ca^{2+}] = K_d(F-F_{min})/(F_{max}-F), \]

where \( K_d \) is 488 nM for fluo-3, and \( F \) is the observed fluorescence level. Each tracing was calibrated for the maximal intensity (\( F_{max} \)) by addition of ionomycin (8µM) and for the minimal intensity (\( F_{min} \)) by addition of EGTA (50 mM) at the end of each measurement.

**Isolation of phagosome and analysis.** Cells were incubated with IgG-opsonized latex bead for 1 hr with a multiplicity of infection (MOI) at 50:1, and washed with PBS. After cell disruption using 30 guage-needle syringes, the latex bead containing phagosomes were isolated on a sucrose gradient (52, 53). The isolated phagosome was washed and resuspended with serum-free media for further use in experiments. For the identification of CD38 localization on the phagosome surface, latex bead-containing phagosomes were permeabilized with 0.1% Triton X-100 in serum-free media at 4 °C for 20 min and fixed with 4% paraformaldehyde. Thereafter, CD38 and MHCIIA were stained with specific antibodies. For immunoblotting, phagosome pellets were dissolved in 4% SDS in...
50 mM Tris-HCl buffer (pH 8.0) by sonication. Solubilized proteins were obtained from the supernatant after centrifugation at 13,300 rpm for 20 min at 4 °C, and were used for immunoblotting.

Measurement of intracellular cADPR concentration ([cADPR]). cADPR was measured by some modification of the cycling method described previously (54). Briefly, after IgG-opsonized latex bead treatment to 2 x 10⁶ cells per microtube at various time intervals, cells were treated with 0.6 M perchloric acid under sonication. Precipitates were removed by centrifugation at 14,000 rpm for 10 min at 4°C. Perchloric acid was removed by mixing the aqueous sample with 3 parts 2M KOHCO₃ with vortex until the top aqueous layer containing cADPR cleared. The samples were then centrifuged at 14,000 rpm for 10 min at 4°C. The top most aqueous layer was collected and neutralized with 0.1 M NaPO₄, pH 8.0, mixed slightly by hand, and then let on ice. To remove all contaminating nucleotides including NAD, but not cADPR, the samples were incubated with the following hydrolytic enzymes overnight at 37°C: 0.44 units/ml nucleotide pyrophosphatase, 12.5 units/ml alkaline phosphatase, 0.0625 units/ml NADase, and 2.5 mM MgCl₂. Enzymes were removed by filtration using a centrifugal filter unit from Millipore (Billerica, MA) at 14,000 xg for 90 min. The filtrate was then collected for measurement of cADPR. To convert cADPR to β-NAD⁺, the samples were incubated at room temperature for 1 hr with the cycling reagent at a 2:1 ratio containing: 0.3 µg/ml ADPR cyclase, 30 mM nicotinamide, and 20 mM NaPO₄ pH 8.0. The samples were further incubated with a cycling reagent at 1:1 ratio containing: 2% ethanol, 100 µg/ml alcohol dehydrogenase, 20 µM resazurin, 10 µg/ml diaphorase, 10 mM nicotinamide, 0.1 mg/ml BSA, 100 mM NaPO₄ pH 8.0, and 10 µM FMN. An increase in the resorufin fluorescence was measured at an excitation of 544 nm and an emission of 590 nm using a SpectraMax Gemini fluorescence plate reader (Molecular Devices Corp.) every 30 min for 3-4 hrs. Various known concentrations of cADPR were also included in the cycling reaction to generate a standard curve.

Measurement of intracellular NAADP concentration ([NAADP]). The level of NAADP was measured using a cyclic enzymatic assay as described previously (55). Briefly, after IgG-opsonized latex bead treatment at various time intervals, cells were treated with 0.6 M perchloric acid under sonication. Precipitates were removed by centrifugation at 14,000 rpm for 10 min at 4°C. Perchloric acid was removed by mixing the aqueous sample with 3 parts 2 M KOHCO₃ with vortex until the top aqueous layer containing cADPR cleared. The samples were then centrifuged at 14,000 rpm for 10 min at 4°C. The top most aqueous layer was collected and neutralized with 0.1 M NaPO₄ pH 8.0, mixed slightly by hand, and then let on ice. To remove all contaminating nucleotides, the samples were incubated with the following hydrolytic enzymes overnight at 37°C: 2.5 units/ml apyrase, 0.125 units/ml NADase, 2 mM MgCl₂, 1 mM NaF, 0.1 mM PPI, and 0.16 mg/ml NMN-AT. Enzymes were removed by filtration using a centrifugal filter unit at 14,000 xg for 90 min. The filtrate was then collected for measurement of NAADP. For conversion of NAADP to NAAD, samples were incubated with 10 units/ml alkaline phosphatase overnight at 37°C. Enzymes were then removed again by filtration. For conversion of NAAD to NAD, the samples were incubated at room temperature for 1 hr with a cycling reagent at a 1:1 ratio containing: 0.2 mg/ml NMN-AT, 0.2 mM NMN, 0.5 mM PPI, 10 nM nicotinamide, 2.0 mM NaF, 2.0 mM MgCl₂, and 100 mM Tris/HCl pH 8.0. The samples were further incubated with a cycling reagent at 1:1 ratio containing: 2%
ethanol, 100 µg/ml alcohol dehydrogenase, 20 µM resazurin, 10 µg/ml diaphorase, 10 µM FMN, 0.1 mg/ml BSA, and 100 mM NaPO₄ pH 8.0. An increase in the resorufin fluorescence was measured at an excitation of 544 nm and an emission of 590 nm using a SpectraMax Gemini fluorescence plate reader every 30 min for 3-4 hrs and once more overnight. Various known concentrations of NAADP were also included in the cycling reaction to generate a standard curve.

Statistical analysis. Data represent means±SEM of at least three separate experiments. Statistical analysis was performed using Student’s t test. A value of P<0.05 was considered significant.

RESULTS

IgG-opsonized Latex Beads Induce FcγR–mediated Phagocytosis via ADPR cyclase activation in J774A.1 Murine Macrophages

We first wanted to prove the possible presence and role of the transmembrane protein CD38 in J774A.1 macrophages during phagocytosis. We ascertained its expression using a NGD⁺ assay which measures the formation of the fluorescent compound, cyclic GDP-ribose (cGDPR), as a result of its ADPR cyclase activity on the surface of the cells (Figure 1A). We examined whether the enzyme activity was reduced by the internalization of CD38 through FcγR–mediated phagocytosis when adding IgG-opsonized 3.0 µm latex beads. This particular size of latex bead was chosen because it was found to have high levels of phagocytic cup formation and no lag in delivery to lysosomes (56). Almost immediately after addition of the opsonized beads, we found that the rate of formation of cGDPR significantly decreased over time with a greatest loss in activity at 15 seconds (Figure 1A) but we did not observe reducing effect of cGDPR formation activity by non-opsonized latex beads, possibly due to the FcγR-mediated internalization of the ADPR cyclase from the plasma membrane for its activation. To visually show that particles can be internalized by FcγR-mediated phagocytosis, we treated J774A.1 macrophages with latex beads with or without opsonization of IgG by incubation for 30 min at 37°C, and we saw that the IgG-opsonized beads had a dramatically higher rate of particle ingestion than the unopsonized beads (Figure 1B). The phagocytosed ratio of non-opsonized LB were very low in comparison in J774.

For further confirmation, we carried out an immunohistochemistry study where we stained for CD38 and MHCIIA (Figure 2). To also verify that the ingested particles were indeed IgG-opsonized latex beads, we coated IgG with TRITC before opsonization. Not only did this make it easier to detect the phagocytosed bead, but it also confirmed that IgG was properly opsonized to the target. In the cells normal state, both CD38 and MHCIIA were found to be located mostly along the plasma membrane (Figure 2A and B). Once FcγR-mediated phagocytosis was initiated with IgG-opsonized latex beads, we found that both CD38 and MHCIIA seemed to internalize along with the opsonized bead (Figure 2A and B), confirming previous observations that CD38 is activated through internalization. We also observed the internalization of CD38 independently of the phagosome as well, while also confirming that the IgG-opsonized latex beads themselves do not emit auto fluorescence that could interfere with the immunohistochemistry interpretation (Figure 2C). To determine the direction of the C-terminus of CD38, which is the active site, we performed immunostaining with a C-terminus specific antibody against CD38 (M-19, SantzCruz) and anti-MHCIIA by permeabilization methods with a mild concentration of detergent. As a result, CD38 was not stained in non-permeabilized phagosomes and co-localized with the IgG-coated surface of the latex beads, whereas MHCIIA was stained in both groups with a similar pattern and co-localized with the IgG-coated surface of the latex beads. CD38 on the
IgG-coated Latex Beads Induce Ca\textsuperscript{2+} Signaling in J774A.1 Macrophages

After witnessing the possible involvement of an ADPR cyclase, we delved deeper into its action by performing Ca\textsuperscript{2+} signaling experiments and measuring the changes in intracellular Ca\textsuperscript{2+}. The Ca\textsuperscript{2+}-sensitive fluorescent dye fluo-3 AM was used with or without pre-treatment of a variety of classical Ca\textsuperscript{2+} signaling inhibitors in J774A.1 macrophages before introducing IgG-opsonized latex beads. The addition of IgG-opsonized latex beads alone without any inhibitors was able to generate typical long-lasting Ca\textsuperscript{2+} signals (Figure 3A). To see if IP\textsubscript{3} is utilized in the Ca\textsuperscript{2+} signaling pathway of Fc\gammaR-mediated phagocytosis, we pre-treated the cells with 2 \muM of xestospongin C (XeC), an IP3 receptor blocker (57), and found that this had no affect on the Ca\textsuperscript{2+} signal (Figure 3B), suggesting that IP\textsubscript{3} is not involved. We previously reported that extracellular cADPR enhanced Fc\gammaR-mediated phagocytosis (25). To corroborate our previous finding that cADPR is involved in Fc\gammaR-mediated phagocytosis, we pretreated our cells with 100 \muM of an antagonistic analog of cADPR, 8-Br-cADPR (58), and we observed that pre-incubation with this inhibitor was able to abolish the long-lasting Ca\textsuperscript{2+} signal (Figure 3C). cADPR is also known to act on RyR for Ca\textsuperscript{2+} release (59). For additional confirmation we used 20 \muM of ryanodine, since it antagonistically binds to RyR on ER/SR Ca\textsuperscript{2+} stores (60). We discovered that this provided very similar results as with 8-Br-cADPR, thus providing some consistency (Figure 3D). Since NAADP is known to be synthesized by CD38, we wanted to see its potential role by pre-incubating our cells with 600 nM of bafilomycin A1 (BafA1), a vacular H\textsuperscript{+} ATPase inhibitor which is required for maintaining acidity of NAADP-sensitive Ca\textsuperscript{2+} stores (61). Surprisingly, this was not able to abrogate the long-lasting phase of the Ca\textsuperscript{2+} signal (Figure 3E). CD38 is known to be activated via its internalization from the plasma membrane through its association with phosphorylated MHCIIA by protein kinase G (23). To verify this notion, we treated J774A.1 macrophages with a specific MHCIIA inhibitor, blebbistatin (62), which completely blocked the IgG-opsonized latex bead-induced Ca\textsuperscript{2+} signaling (Figure 3F). These findings reveal that Fc\gammaR-mediated phagocytosis by way of IgG-opsonized latex beads induce Ca\textsuperscript{2+} signaling that is mediated by CD38/cADPR.

Ca\textsuperscript{2+} Signaling Inhibitors Greatly Reduce Fc\gammaR-mediated Phagocytosis in J774A.1 Murine Macrophages

Based on the Ca\textsuperscript{2+} signaling data, we proceeded to further quantify our results by calculating the phagocytic index of J774A.1 macrophages incubated under varying conditions for 30 min at 37\degreeC before inducing phagocytosis with IgG-opsonized latex beads (Figure 4). Through microscopic imaging, we found that pre-incubation with BafA1 and XeC did not significantly affect phagocytic capability, where full ingestion of IgG-opsonized latex beads was seen as in the un-treated J774A.1 cells. This is concordant with our previous Ca\textsuperscript{2+} measurement data where these two inhibitors had no affect on the signaling. On the other hand, we observed a notable 46% decrease of phagocytosis when cells were pre-incubated with 8-Br-cADPR where IgG-opsonized latex beads were seen mostly attached to the outer periphery of macrophages and full internalization of the beads were decreased. Similar results were also obtained when macrophages were pre-incubated with the...
MHCIIA inhibitor, blebbistatin, where we found a 49% decrease. These observations affirm that cADPR is involved in FcγR-mediated phagocytosis in J774A.1 macrophages and NAADP seems to not be a part of this particular signaling system.

\[ \text{J774A.1 Macrophages Utilize Store-operative \( \text{Ca}^{2+} \) Entry} \]

It has been reported that store-operative \( \text{Ca}^{2+} \) entry (SOCE) may be involved in macrophage phagocytosis (63-67). To see which intracellular \( \text{Ca}^{2+} \) stores were present within J774A.1 cells, \( \text{Ca}^{2+} \) measurement was done on thapsigargin-induced \( \text{Ca}^{2+} \) release in a \( \text{Ca}^{2+} \)-free buffer, where thapsigargin is a sarco/endoplasmic reticulum \( \text{Ca}^{2+} \) ATPase (SERCA) inhibitor (67). This was able to cause a rapid release of \( \text{Ca}^{2+} \) from ER/SR stores, indicating their presence in the intracellular space (Figure 5A). The addition of extracellular \( \text{Ca}^{2+} \) was also able to elicit a rapid influx of \( \text{Ca}^{2+} \), suggesting the presence of \( \text{Ca}^{2+} \) channels. To see the contribution of acidic-like organelles, we performed \( \text{Ca}^{2+} \) measurements on GPN-induced \( \text{Ca}^{2+} \) release in a \( \text{Ca}^{2+} \)-free buffer as well (Figure 5B). Unlike the thapsigargin-induced \( \text{Ca}^{2+} \) release, we were not able to detect any noticeable releases of intracellular \( \text{Ca}^{2+} \), and the addition of extracellular \( \text{Ca}^{2+} \) did not cause any influx. This indicates a lack of role of acidic-like organelles as an intracellular \( \text{Ca}^{2+} \) store, which remains consistent with our earlier \( \text{Ca}^{2+} \) measurement where BafA1 had no affect on FcγR-mediated phagocytosis.

To see which \( \text{Ca}^{2+} \) channels were involved, we performed \( \text{Ca}^{2+} \) measurement experiments using different \( \text{Ca}^{2+} \) channel blockers. We first preincubated J774A.1 macrophages with 10 \( \mu \text{M} \) nifedipine, which is a voltage-dependent L-type \( \text{Ca}^{2+} \) channel blocker (68). Surprisingly, this was not able to abrogate any increases of \([\text{Ca}^{2+}]_{\text{i}}\), in the cells (Figure 5C). As a result, we used 50 \( \mu \text{M} \) of another \( \text{Ca}^{2+} \) channel blocker, SK&F 96365, which also inhibits SOCE (69). Interestingly, this was able to abolish the \( \text{Ca}^{2+} \) signal; however, we were able to detect an initial sharp rise in \( \text{Ca}^{2+} \) (Figure 5D). This similar pattern was also observed when the cells were treated in a \( \text{Ca}^{2+} \)-free buffer with 0.5 mM EGTA and was completely inhibited when treated in a \( \text{Ca}^{2+} \)-free buffer with 100 \( \mu \text{M} \) Fura-2AM (Figure 5E), suggesting that the main method of \( \text{Ca}^{2+} \) influx from the extracellular environment may be mediated through the emptying of intracellular \( \text{Ca}^{2+} \) stores, hinting at a store-operated mechanism. To determine if the initial \( \text{Ca}^{2+} \) peak is mediated by cADPR, J774A.1 cells were incubated with both SK&F 96365 and 8-Br-cADPR (Figure 5F). Our results showed that this was able to effectively block any \([\text{Ca}^{2+}]_{\text{i}}\), rise in the cells. This outcome made us conclude that SOCE is involved during FcγR-mediated phagocytosis, where the initiator of extracellular \( \text{Ca}^{2+} \) influx is cADPR-mediated \( \text{Ca}^{2+} \) release from ER/SR stores.

To further explore the possible involvement of SOCE, various SOCE inhibitors were also pre-incubated with J774A.1 cells and the phagocytic index was again measured (Figure 5H). The SOCE channel blocker SK&F 96365 and thapsigargin were able to greatly reduce the number of internalized beads by 38% and 47% respectively. The same was also seen when the phagocytic index was determined in a \( \text{Ca}^{2+} \)-free buffer with a 34% decrease in bead ingestion. These results further affirm our conclusion that FcγR-mediated phagocytosis in J774A.1 macrophages is controlled by both the mobilization of \( \text{Ca}^{2+} \) from intracellular \( \text{Ca}^{2+} \) stores as well as the influx of \( \text{Ca}^{2+} \) from the extracellular space through a \( \text{Ca}^{2+} \) channel.

\[ \text{FcγR} \-mediated Phagocytosis Induces cADPR Formation in J774A.1 Macrophages} \]

Since our \( \text{Ca}^{2+} \) signaling data exhibited that 8-Br-cADPR was able to ablate the somewhat long-lasting \( \text{Ca}^{2+} \) signal and substantially reduce the phagocytic index, these considerations propelled us to measure \([\text{cADPR}]_{\text{i}}\) in J774A.1 macrophages after initiating FcγR-mediated phagocytosis with IgG-opsonized latex beads.
We measured [cADPR] within a time course and saw a significant rise in [cADPR] within the first 5 seconds after IgG-opsonized latex bead addition, where levels remained elevated until 20 seconds, after which [cADPR] tapered off to resting values (Figure 6A). Interestingly, we were able to see a rise in [cADPR] with unopsonized latex beads as well, although this increase was very slight, suggesting the possible involvement of cADPR in non-FcγR-mediated phagocytosis.

The use of BafA1 had no notable effects on both Ca²⁺ signaling and the phagocytic index of J774A.1 macrophages. To validate these observations, we also measured [NAADP]. Unsurprisingly, we were not able to detect any noticeable levels of [NAADP], after evoking phagocytosis (Figure 6B). This result remains in accordance with another finding that [NAADP], is not detected in J774A.1 macrophages using another NAADP measurement method (70-71). These aforementioned data made us conclude that FcγR-mediated phagocytosis with IgG-opsonized latex beads induces cADPR, but not NAADP, production.

**IgG-opsonized Latex Beads Induces Ca²⁺ Signaling in Wild-Type but not in CD38⁻/⁻ Mice**

Since we have now established the role of Ca²⁺ signaling and a possible ADPR cyclase, such as CD38, in murine macrophage phagocytosis in an established cell line, we then tested these same principles ex vivo between wild-type and CD38⁻/⁻ mice. Ca²⁺ signaling data using IgG-opsonized latex beads on extracted wild-type macrophages showed a typical Ca²⁺ response involving an initial and a somewhat long-lasting signal (Figure 7A), very similar to what was previously noted in normal J774A.1 cells. The same Ca²⁺ signaling measurements were then performed on extracted CD38⁻/⁻ macrophages, where we observed total ablation of any Ca²⁺ signal (Figure 7B). These results suggest that CD38 is a possible candidate as an ADPR cyclase that is responsible for producing the Ca²⁺ signaling messengers necessary for allowing a rising level of [Ca²⁺].

**CD38⁻/⁻ Mouse Macrophage Has Greatly Reduced FcγR-mediated Phagocytosis**

The results of our Ca²⁺ signaling data in both wild-type and CD38⁻/⁻ macrophages prompted us to visually examine the differences in FcγR-mediated phagocytosis. Microscopic images of wild-type macrophages clearly show full engulfment of IgG-opsonized latex beads (Figure 7C). Macrophages obtained from CD38⁻/⁻ mice, however, showed a markedly impaired ability of the cells to commence phagocytosis, where little ingestion of opsonized particles was seen (Figure 7C). Quantification of the data reveals that CD38⁻/⁻ macrophages has a considerable decrement in the phagocytic index of over 50% when compared to wild-type macrophages (Figure 7D). This outcome again intimates that CD38 is the ADPR cyclase accountable for phagocytosis mediated by FcγR.

**CD38-deficiency Leads to a Decreased Phagocytosis In Vivo.**

We further examined whether CD38-deficiency leads to compromising phagocytosis for live bacteria. We injected mice s.c. with *M. bovis* BCG and three weeks later, injected i.p. with opsonized *M. bovis* BCG and compared phagocytic *M. bovis* BCG in peritoneal macrophages isolated after bacterial injection. Wild-type macrophages showed phagocytosed *M. bovis* BCG, whereas macrophages obtained from CD38⁻/⁻ mice showed a significantly reduced phagocytic ingestion of *M. bovis* BCG (Figure 8A). Flow cytometric analysis of phagocytic *M. bovis* BCG with biotinylated rabbit anti-BCG polyclonal antibody also shows no detectable phagocytic signal in macrophages obtained from CD38⁻/⁻ mice compared to that in macrophages obtained from Wild-type mice (Figure 8B).

**DISCUSSION**
In the present study, our data clearly shows the crucial role that CD38 has to play in regulating Ca\textsuperscript{2+} signals that is necessary for Fc\gamma R-mediated phagocytosis of IgG-opsonized latex beads. This is made possible through its internalization where the production of cADPR, but not NAADP, is allowed to take place. Although the role of IP\textsubscript{3}, cADPR, and CD38 has been implied for immune cells in other works, a detailed investigation of the direct relationship between CD38 and Fc\gamma R-mediated phagocytosis in murine macrophages has not yet been made clear. We are also the first to show ex vivo the importance of CD38 and its necessary involvement in phagocytosis, where macrophages prepared from CD38\textsuperscript{-/-} mice showed a non-existent Ca\textsuperscript{2+} signal as well as a drastically reduced uptake of IgG-opsonized latex beads as well as live bacteria. This is consistent with the phenotypic traits of CD38\textsuperscript{-/-} mice where they tend to be more susceptible to infection, and thus have a weaker survival rate (72). This could be due to the reduced ability for immune cells such as macrophages to uptake foreign microbes.

This is the first time to our knowledge that anyone has shown the possibility of CD38 being internalized along with the phagosome as it is endocytosed. It must be noted however that this was not always seen in our case, where we also observed the internalization of CD38 independently of the ingested IgG-opsonized latex bead. This internalization may be important in the physiological aspect because this will allow the rise in [Ca\textsuperscript{2+}], to be more localized, as seen in other Ca\textsuperscript{2+} studies with phagocytosis where there are spatial and temporal aspects to the signaling (72, 73), thus allowing for better control during phagocytic ingestion. This may be important for downstream effectors as a result of the increase in [Ca\textsuperscript{2+}], such as Ca\textsuperscript{2+}-dependent gelsolin, an actin-binding protein, which has been documented to play a part in actin remodeling through assembly/disassembly during phagocytosis (29, 74-77). Whether there is a direct relationship between the Ca\textsuperscript{2+} that is induced by the CD38 product cADPR and gelsolin activity is highly likely, but remains to be confirmed.

CD38 being internalized along with the phagosome-containing IgG-opsonized particles may have implications in not only phagocytic ingestion, but in phagosome maturation as well. In one study with monocytes, a thin rim of high [Ca\textsuperscript{2+}] was noted surrounding the phagosome of the ingested opsonized particles (76). We also observed this more localized form of [Ca\textsuperscript{2+}], increase, unlike the more global rises seen in other systems. This confined Ca\textsuperscript{2+} around the phagosome during the later stages of phagocytosis has been implicated in oxidative enzyme-containing vesicle fusion with the phagosome (14, 27, 31), as well as ROS production (77-79) where blocking Ca\textsuperscript{2+} at this point impairs both. During these processes, it is possible that CD38 may be an important player in providing the Ca\textsuperscript{2+} necessary for these events to take place, where its internalization can continue to produce cADPR at the local level.

Rapid cADPR production was seen during Fc\gamma R-mediated phagocytosis within a few seconds after initiation. This coincides with our NGD\textsuperscript{+} assay where surface ADPR cyclase activity decreased in a time-dependent manner, as well as our [Ca\textsuperscript{2+}] level measurements where it increased. This may seem contradictory especially in the context where it has been reported that it can take anywhere from 30 seconds to a few minutes for the actual phagocytosis process to begin (80). However; it must be again noted that CD38 can be internalized independently from the opsonized particles, as we have observed. So while the IgG-opsonized latex bead is being phagocytosed after binding to Fc\gamma Rs, this can send a signaling cascade to the other surrounding CD38 to internalize, presumably via endosomes (81). This is what may be responsible for the quick production of cADPR, so that early Ca\textsuperscript{2+} signals can be generated in preparation for phagocytosis to take place. At present, we were not able to
detect any distinguishable levels of NAADP, suggesting that Ca\(^{2+}\) generation in Fc\(\gamma\)R-mediated phagocytosis in murine macrophages relies solely on the action of cADPR on ER/SR Ca\(^{2+}\) stores.

SOCE seems to work synergistically with the release of intracellular Ca\(^{2+}\) from ER/SR stores with cADPR being the initiator of this Ca\(^{2+}\) mobilization. This is attributed to the fact that SOCE inhibitor SK&F 96365 in combination with 8-Br-cADPR effectively diminishes [Ca\(^{2+}\)]\(_i\) levels and reduces the rate of IgG-opsonized latex bead phagocytic uptake. The usage of the L-type Ca\(^{2+}\) channel blocker nifedipine did not affect [Ca\(^{2+}\)]\(_i\) levels in our study, suggesting that the Ca\(^{2+}\) channels contains characteristics that are more receptor-mediated or SOCE rather than voltage-gated. This is in accordance with another study where the usage of SK&F 96365 was able to eliminate the later rise in [Ca\(^{2+}\)]\(_i\) levels and where another L-type Ca\(^{2+}\) channel blocker verapamil had no effect on Listeria monocytogenes-induced phagocytosis in J774 murine macrophages (81, 82). The exact mechanism of intracellular Ca\(^{2+}\) store depletion-induced Ca\(^{2+}\) influx and the nature of the Ca\(^{2+}\) channel present on the cellular membrane remain yet to be discovered. Other Ca\(^{2+}\) channels such as Orai1 (83) and the ER Ca\(^{2+}\)-sensing protein STIM1 (61) have been implied to be involved in various immune cells. Whether or not CD38 works in tandem with these proteins and channels should warrant further investigation.

The main focus of this study was to investigate the role of CD38 in Fc\(\gamma\)R-mediated phagocytosis in the murine macrophage-like cell line J774A.1. We demonstrated that Fc\(\gamma\)R activation during IgG-opsonized latex bead ingestion elicits Ca\(^{2+}\) signaling through the production of cADPR by the internalization of the transmembrane ADP ribosyl cyclase CD38. While the involvement of Ca\(^{2+}\) in phagocytosis is still up for debate, it should be indicated that there are countless of factors that affect macrophage phagocytosis, as well as other Ca\(^{2+}\) signaling pathways that are involved in the process that are not strictly Fc\(\gamma\)R-mediated (84-88). Therefore, amidst all the various works presently on Ca\(^{2+}\)-mediated phagocytosis, this study provides new perspectives in immune defense by introducing the involvement of the ADPR cyclase CD38, and can help shed light on developing novel methods or drugs that can help contain bacterial infections.

FIGURE 1. IgG-opsonized latex beads induce FcγR-mediated phagocytosis via ADPR-cyclase activation in J774A.1 murine macrophages. ADPR-cyclase activity was assessed in J774A.1 murine macrophages through an NGD⁺ assay where 200 µM of NGD⁺ was used as a substrate as described in EXPERIMENTAL PROCEDURES. (A) Decrease in ADPR-cyclase activity at the membrane
surface was observed in a time-dependent manner after initiating FcγR-mediated phagocytosis with IgG-opsonized latex beads. The data represent mean ±S.D. cGDP synthesis of three experiments. *p<0.05 versus zero time, and **p<0.01 versus zero time. Closed squares and closed circles are latex bead and IgG-opsonized latex bead groups, respectively. (B) Unaffected J774A.1 macrophages (upper-left panel) were preincubated with 3.0 µm latex beads without IgG opsonization (LB) (upper-right panel) or with IgG opsonization (IgG-LB) (lower-left panel) for 30 min at 37°C in 5% CO₂ (magnification ×40). (lower-right panel) Statistic analysis of phagocytosis in J774A.1 cells. #p<0.001 vs no-ingested latex bead group of J774A1 cells.

FIGURE 2. Two or three dimensional fluorescence images of CD38 and myosin heavy chain IIA in J774A.1 murine macrophages. CD38 and MHCIIA internalization via FcγR-mediated phagocytosis was visualized through immunohistochemistry with a primary FITC conjugated rat anti-mouse CD38 or a rabbit polyclonal MYH9 antibody respectively as described in EXPERIMENTAL PROCEDURES. (A) CD38 (green) was found to be situated along the plasma membrane in its resting state (control). Initiation of FcγR-mediated phagocytosis with TRITC IgG-opsonized latex beads (red) resulted in CD38 internalization where it co-localized with the phagosome. (B) MHCIIA (green) was also found to be situated along the plasma membrane in its resting state (control). Initiation of FcγR-mediated phagocytosis with TRITC IgG-opsonized latex beads (red) resulted in MHCIIA internalization where it also co-localized with the phagosome. (C) CD38 (green) also internalizes independently of the phagosome after initiating FcγR-mediated phagocytosis with IgG-opsonized latex beads. Blue line shows the position of the phagosome on the z-axis. X (green line), y (red line) image is the confocal z-axis slice corresponding to the position of the blue line (i.e. through the center of the phagosome). The phagosome is stably positioned within the cell. (D) Co-localized images of CD38 or MHCIIA with phagocytosed-latex bead. Latex bead-containing phagosomes were isolated as described in EXPERIMENTAL PROCEDURES and stained with anti-CD38 and anti-MHCIIA antibodies with or without permeabilization. (E) Western blot of CD38 and IgG with biotinylated anti-CD38 antibody and anti-mouse IgG antibody on latex beads (LB), latex bead-containing phagosome (phagosome LB), and whole lysate of J774A.1 cells.

FIGURE 3. IgG-opsonized latex beads induce Ca^{2+} signaling in J774A.1 murine macrophages. [Ca^{2+}]_i measurements in FcγR stimulation was determined by a confocal microscope on J774A.1 cells preincubated with Fluo-3 AM as described in EXPERIMENTAL PROCEDURES. (A) IgG-opsonized latex beads induces a rapid rise in [Ca^{2+}]_i, whereas un-opsonized latex beads do not elicit Ca^{2+} signaling. (B) Effect of 2 µM xestospongin C, (C) 100 µM 8-Br-cADPR, (D) 20 µM Ryanodine, (E) 600 nM bafilomycin A1, (F) and 50 µM blebbistatin on FcγR stimulation-induced [Ca^{2+}]_i increase in J774A.1 murine macrophages. Arrows indicate time point of un/opsonized latex bead addition. (G) A direct comparison of Ca^{2+} levels at 15 s after treatment of LB or IgG-LB. Each line represents mean ±S.D. of [Ca^{2+}]_i from minimum 3 independent experiments. *p<0.01 and **p<0.05 vs LB treated group, #p<0.01 vs IgG-LB group.

FIGURE 4. Ca^{2+} signaling inhibitors greatly reduce FcγR-mediated phagocytosis in J774A.1 murine macrophages. Phagocytic index was assessed by plating J774A.1 murine macrophages in 6-well
plates and preincubating with the following inhibitors for 30 min as described in EXPERIMENTAL PROCEDURES: 600 nM bafilomycin A1, 2 μM xestospongin C, 100 μM 8-Br-cADPR, or 50 μM blebbistatin (magnification x40). The data represent mean ± S.D. of phagocytic ingestion of five experiments. *p<0.01 and **p<0.001 versus IgG-opsonized latex beads (IgG-LB).

FIGURE 5. J774A.1 murine macrophages utilize store-operated Ca\(^{2+}\) entry. [Ca\(^{2+}\)]\(_i\) measurements in FcγR stimulation to determine possible SOC mechanisms was determined by a confocal microscope on J774A.1 cells preincubated with Fluo-3 AM as described in EXPERIMENTAL PROCEDURES. (A) J774A.1 murine macrophages were stimulated with 1 μM thapsigargin or (B) 50 μM GPN in the absence of extracellular calcium and 5 minutes later, 1 mM CaCl\(_2\) was added to the medium. First arrow indicates time point of thapsigargin/bafilomycin addition. Second arrow indicates time point of 1 mM Ca\(^{2+}\) addition. [Ca\(^{2+}\)]\(_i\) measurements in FcγR stimulation was further analyzed by preincubating cells with (C) 10 μM nifedipine, (D) 50 μM SK&F 96365, (E) Ca\(^{2+}\)-free buffer supplemented with 0.5 mM EGTA, (F) and 50 μM SK&F 96365 with 100 μM 8-Br-cADPR. Arrows indicate time point of opsonized latex bead addition. Each line represents mean ± S.D. of [Ca\(^{2+}\)]\(_i\) from minimum 3 independent experiments. (G) A direct comparison of Ca\(^{2+}\) levels at 15 s after treatment of LB or IgG-LB. (H) Phagocytic index was assessed by platting J774A.1 murine macrophages in 6-well plates and preincubating with the following inhibitors for 30 min as described in Materials and Methods: 1 μM thapsigargin, 50 μM SK&F 96365, Ca\(^{2+}\)-free buffer supplemented with 0.5 mM EGTA, or Ca\(^{2+}\)-free buffer supplemented with 100 μM Fura-2AM (magnification x40). The data represent mean ± S.D. of phagocytic ingestion of five experiments. ¶p<0.01 and ¶¶p<0.001 versus IgG-opsonized latex beads (IgG-LB).

FIGURE 6. FcγR-mediated phagocytosis induces cADPR formation in J774A.1 murine macrophages. [cADPR]\(_i\) and [NAADP]\(_i\) was measured immediately after the addition of latex beads with or without IgG opsonization using a cycling assay as described in EXPERIMENTAL PROCEDURES. (A) [cADPR]\(_i\) increased in a time dependent manner after initiating FcγR-mediated phagocytosis with IgG-opsonized latex beads. *p<0.01 versus unopsonized latex beads (Control LB). (B) [NAADP]\(_i\) increase was not detected after initiating FcγR-mediated phagocytosis with IgG-opsonized latex beads. Each line represents mean ± S.D. of cADPR or NAADP formation from 3 independent experiments each.

FIGURE 7. CD38\(^{-/-}\) mice macrophages have greatly reduced FcγR-mediated Ca\(^{2+}\) signals and phagocytosis. [Ca\(^{2+}\)]\(_i\) measurements in FcγR stimulation was determined by a confocal microscope on (A) macrophages prepared from CD38\(^{+/+}\) mice and (B) CD38\(^{-/-}\) mice with LB or IgG-LB. Arrows indicate time point of un/opsonized latex bead addition. Each line represents mean ± S.D. of [Ca\(^{2+}\)]\(_i\) from minimum 3 independent experiments. Phagocytosis was visualized by light microscopy in (C) macrophages prepared from CD38\(^{+/+}\) mice (upper panel) and CD38\(^{-/-}\) mice (lower panel) (magnification ×40). (D) Quantification of the phagocytic index using opsonized (IgG-LB) or unopsonized (LB) latex beads in macrophages extracted from CD38\(^{+/+}\) or CD38\(^{-/-}\) mice. The data represent mean ± S.D. of phagocytic ingestion of five experiments (n=15). *p<0.001 versus wild-type
unopsonized latex bead (CD38+/+-LB), **p<0.05 versus CD38+/+ unopsonized latex beads (CD38+/+IgG LB), and #p<0.01 versus CD38+/+IgG opsonized latex beads (CD38+/+IgG-LB).

FIGURE 8. CD38-deficiency leads to decreased phagocytosis in vivo. CD38+/+ and CD38-/- mice (each, n=5) were injected s.c. with M. bovis BCG (1×10⁷ CFU/mouse). Three weeks later, mice were injected i.p. with opsonized M. bovis BCG (1×10⁷ CFU/mouse). Peritoneal macrophages were then isolated at 24 h after bacterial injection and stained with fluorescent auramine-rhodamine. (A) Cells containing phagocytic M. bovis BCG in 5 different fields for each condition were counted. Representative immunofluorescence images of three independent replicates are shown (inset). Scale bars = 10 μm. Arrow indicates auramine-rhodamine stained M. bovis BCG. (B) Flow cytometric analysis of phagocytic M. bovis BCG with biotinylated rabbit anti-BCG polyclonal antibody. Biotinylated antibody was detected with streptavidine-cy3 and analyzed with a flow cytometer. Streptavidine-Cy3 only was stained (blue line); biotinylated anti-BCG antibody and streptavidine-Cy3 were stained (red line). Data are expressed as mean ± S.D. (*p < 0.001, versus CD38+/+) (n=5).
