The abbreviations used are: topo, topoisomerase.

**Background:** New antibacterial compounds are urgently needed; DNA gyrase is a well-validated target.

**Results:** Diospyrin and other naphthoquinones inhibit DNA gyrase by binding to a novel site in the B subunit.

**Conclusions:** Naphthoquinones are inhibitors of gyrase with a novel mechanism of action.

**Significance:** Naphthoquinones have potential as antibacterial compounds against TB.

**SUMMARY**

Tuberculosis and other bacterial diseases represent a significant threat to human health. The DNA topoisomerases are excellent targets for chemotherapy and DNA gyrase in particular is a well-validated target for antibacterial agents. Naphthoquinones (e.g. diospyrin and 7-methyljuglone) have been shown to have therapeutic potential, particularly against *Mycobacterium tuberculosis*. We have found that these compounds are inhibitors of the supercoiling reaction catalyzed by *M. tuberculosis* gyrase and other gyrase. Our evidence strongly suggests that the compounds bind to the N-terminal domain of GyrB, which contains the ATPase active site, but are not competitive inhibitors of the ATPase reaction. We propose that naphthoquinones bind to GyrB at a novel site close to the ATPase site. This novel mode of action could be exploited to develop new antibacterial agents.

Infectious diseases caused by bacterial pathogens are a serious and growing problem. For example, tuberculosis (TB) is the most deadly infectious disease in the world with ~2 billion people infected and over 1 million deaths every year (1). Current treatments involve therapy over a long period (~6 months) and there are serious problems with drug-resistant strains (MDR- and XDR-TB). One strategy for developing new antibacterials is to seek new targets. However, despite more than a decade of research driven by genomics and proteomics, and enormous expenditure, very few promising new targets have emerged. It appears that Nature, through millions of years of evolutionary warfare, has already identified the ‘good bacterial targets’, these include the ribosome, cell wall synthesis enzymes and DNA gyrase (2).

DNA gyrase is a DNA topoisomerase that is present in bacteria and plants, but not animals, and has been widely exploited as a target for antimicrobial chemotherapy (3,4). DNA topoisomerases are enzymes that catalyze changes in the topology of DNA and are essential to all cells (5). They are classified into two types, depending upon whether their reactions involve transient single- (type I) or double- (type II) strand breaks in DNA. All topoisomerases can relax supercoiled DNA but
gyrase, a type II enzyme, can also introduce negative supercoils in a reaction coupled to ATP hydrolysis (4,5). Gyrase consists of two subunits, GyrA and GyrB, which form an A2B2 complex in the active enzyme in which a segment of DNA is wrapped around the protein. The GyrA subunit interacts with DNA and contains the active-site tyrosine responsible for DNA cleavage and the formation of a protein-DNA covalent bond during the reaction cycle. GyrB also interacts with DNA and contains the ATPase active site. Gyrase shares a number of features with other type II topoisomerases but is distinct in its ability to wrap DNA and harness the free energy of ATP hydrolysis to introduce negative supercoils into DNA. The uniqueness of gyrase has made it a successful target for antibacterial agents. Fluoroquinolones (e.g. ciprofloxacin, moxifloxacin) target gyrase and are highly-successful clinical agents that have been used against tuberculosis. However, despite their efficacy, fluoroquinolone-resistant TB is a serious problem (6).

Most of our current information about DNA gyrase concerns the Escherichia coli enzyme, but it is clear that enzymes from other bacteria have important differences that need to be investigated in order to exploit their potential as drug targets for specific diseases. DNA gyrase from Mycobacterium tuberculosis has a number of distinct features that warrant investigation in their own right and that may be exploitable for the targeting of this enzyme (7,8). For example, M. tuberculosis gyrase has been found to be a potent decatenase, in contrast to most other gyrase (8-10), reflecting the fact that M. tuberculosis lacks topo IV, which is the predominant decatenating enzyme in most bacteria (11). Recent advances in M. tuberculosis gyrase have included the structures of the N- and C-terminal domains of GyrA and the C-terminal domain of GyrB (12-14), the identification of DNA-binding residues in the C-terminal domain of GyrA (15), and the development of monoclonal antibodies that specifically target the enzyme as potential therapeutic agents (16). Recently a potential Ca2+-binding site has been identified in M. tuberculosis GyrA, which may have a regulatory role (17).

Extracts from plants used in traditional medicine provide a source for novel compounds that may have antibacterial properties. Lall and Meyer have analyzed the antibacterial properties of the S. African tree Euclea natalensis. This plant, also known as the "toothbrush tree" (native S. Africans use its twigs as toothbrushes), has been used extensively to treat a variety of medical complaints (e.g. bronchitis, pleurisy, venereal disease) and in oral health (18). Lall & Meyer showed that crude extracts from E. natalensis were active against drug-sensitive and drug-resistance strains of M. tuberculosis (19). They later reported that the active component in these extracts was the naphthoquinone diospyrin (Fig. 1) (20). Naphthoquinones are widely distributed in nature and their presence in many plants is the basis for some folk medicines (21). They have been implicated in the treatment of a variety of diseases including urinary tract infections, trypanosome diseases and tuberculosis (21,22). Diospyrin, a bisnaphthoquinone (Fig. 1), has previously been found to be an inhibitor of DNA topoisomerase (topo) I from Leishmania donovani and can stabilize the topo I-DNA cleavage complex (23); isodospyrin was found to be an inhibitor of human topo I, but did not stabilize the cleavage complex (24); 7-methyljuglone was shown to be a subversive substrate for M. tuberculosis mycothiol disulfide reductase (25). In addition, there are a number or reports of quinolones interacting with eukaryotic type II topoisomerases (e.g. human topo IIα). For example, several naphthoquinones, including juglone, have been shown to inhibit topo II and stabilize the cleavage complex (26); these compounds react with thiol groups on the protein. The lack of a clear target definition and the observation of the efficacy of diospyrin against drug-sensitive and drug-resistance strains of M. tuberculosis (19), prompted us to test this and other naphthoquinones against M. tuberculosis DNA gyrase. We have found that these compounds can inhibit gyrase and that they target the enzyme by a novel mechanism, raising the possibility of developing these compounds as potential anti-TB agents.

**EXPERIMENTAL PROCEDURES**

Enzymes and DNA – M. tuberculosis and E. coli gyrases and the N-terminal domain of E. coli GyrB (GyrB43) were prepared as described previously (17,27,28). S. aureus WCUH29 gyrA, gyrB, parC, and parE genes in pET vectors were gifts from Hiroshi Hiasa (Univ. Minnesota). They were re-cloned into plasmid pET11 (Novagen) and the proteins expressed in E. coli Rosetta 2 (DE3) pLysS (Novagen). Both proteins were purified using an ÄktA system (GE Healthcare) using Q-Sepharose, heparin-
Enzyme assays - *M. tuberculosis* gyrase supercoiling, relaxation and decatenation assays were carried out as described previously (17); cleavage assays were carried out as per relaxation assays (+/-ATP) except that following incubation at 37°C, SDS and proteinase K were added (to 0.2% and 0.1 mg/mL respectively) and the incubation was continued at 37°C for 30 mins before loading onto an agarose gel for analysis. *E. coli* gyrase supercoiling assays were performed as described (29). *S. aureus* gyrase and topo IV assays were carried out as described (30), apart from the buffer exchange step prior to electrophoresis, which was omitted; samples were loaded onto agarose gels and left for 30 mins prior to electrophoresis in order to allow diffusion of salt. ATPase assays were performed using a linked assay as described (27), except that assays were carried out in microtitre plates and A$_{340}$ measured continuously using an absorbance plate reader. Limited proteolysis experiments were performed as described previously (17).

Mass spectrometry and SPR – Nanoflow electrospray ionization mass spectrometry (nanoESI MS) and surface plasmon resonance (SPR) experiments were performed as previously described (31,32), with the exception that SPR data collection used a Biacore T-100 instrument (GE Healthcare) and regeneration was carried out with 4.5 mM sodium hydroxide. Protein and drug stock solutions were filtered through 0.1 micron spin filters (Merck Millipore) prior to injection over the chip surface to prevent damage to the microfluidics caused by insoluble aggregates. Data was analyzed was using the BIAEvaluation software and displayed using Sigma Plot (Systat Software Inc.).

**RESULTS**

**Inhibition of DNA Gyrase by Naphthoquinones** - In order to determine whether diospyrin and 7-methyljuglone might target *M. tuberculosis* DNA gyrase, we assessed their effect on the gyrase supercoiling reaction (Fig. 2). Both compounds inhibit this reaction with IC$_{50}$s of ~15 µM (diospyrin) and ~30 µM (7-methyljuglone); other naphthoquinones were also tested in this reaction (Table 1; the IC$_{50}$ of novobiocin and ciprofloxacin against *M. tuberculosis* gyrase are given for comparison). We tested diospyrin against *M. tuberculosis* gyrase in relaxation reactions and found that this reaction is also inhibited by this compound with a similar IC$_{50}$ as for supercoiling (Fig. S1). We also tested diospyrin and 7-methyljuglone for their ability to inhibit DNA supercoiling by *E. coli* and *Staphylococcus aureus* gyrases. We found that both these enzymes were inhibited by these compounds with approximate IC$_{50}$s as follows: *E. coli* 4 µM (diospyrin) and 30 µM (7-methyljuglone); *S. aureus*: 8 µM (diospyrin) and 60 µM (7-methyljuglone); (Table 2 & Fig. S2).

As our assays contain 4 mM DTT (i.e. reducing conditions) and it has been reported that quinone inhibitors of topo II are less active under reducing conditions (33), we attempted to carry out experiments without reducing agents. However, we found that *M. tuberculosis* gyrase was inactive in the absence of reducing agents and even with 50 µM DTT showed no activity (data not shown). *M. tuberculosis* gyrase supercoiling assays carried out with diospyrin and 7-methyljuglone in the presence of 2 mM β-mercaptoethanol gave similar results to those carried out with 4 mM DTT. In contrast we have found that *S. aureus* gyrase is active in the presence of a low concentration of DTT (50 µM) and we found similar inhibition by diospyrin and 7-methyljuglone as we had found at 4 mM DTT (data not shown). Taken together, it seems that there is no significant effect of reducing agents on the inhibitory effects of diospyrin and 7-methyljuglone for gyrase.

DNA topoisomerase IV (topo IV) is also the target of a number of antibacterial agents (34,35), however *M. tuberculosis* lacks this enzyme (36); *M. tuberculosis* gyrase has evolved to carry out activities catalyzed by gyrase and topo IV in other bacteria. We tested naphthoquinones against *S. aureus* topo IV and found that in general naphthoquinones favored gyrase over topo IV, for example the IC$_{50}$ for diospyrin is 4-8 times higher for *S. aureus* topo IV than for gyrase (Table S1).

The success of fluoroquinolones, such as ciprofloxacin, as antibacterial agents is due to the fact that they stabilize the cleavage complex between gyrase and DNA (37-39), in which the GyrA protein is covalently attached to the 5’-end of the cleaved DNA. We tested diospyrin and 7-methyljuglone in cleavage-complex assays under conditions (+/- ATP) where ciprofloxacin stabilizes the cleavage complex between *M. tuberculosis* gyrase and DNA. We found no evidence of stabilization of the gyrase-DNA cleavage complex by these agents (data not shown); this is in contrast with results obtained with naphthoquinones (e.g. juglone) and topo II (26).
The fact that diospyrin inhibits ATP-independent relaxation by gyrase suggests that naphthoquinones are unlikely to be ATPase inhibitors. We tested dioxytin in gyrase supercoiling reactions at a range of ATP concentrations (Fig. 3). (This approach has been used previously to show that simocyclinones are not inhibitors of the ATPase reaction of gyrase (32).) We found that whereas inhibition by novobiocin (a well-established inhibitor of the gyrase ATPase reaction) could be abrogated by ATP, inhibition by dioxytin and simocyclinone could not; supporting the contention that dioxytin is not a competitive inhibitor of the gyrase ATPase reaction. We directly tested the effect of dioxytin on the ATPase reaction of *M. tuberculosis* GyrB, but we found that the intrinsic ATPase activity of this protein to be very low, making this experiment problematic (data not shown). However, we found that the ATPase activity of *S. aureus* GyrB could be measured more readily and showed that, whereas this reaction is completely inhibited by novobiocin, dioxytin could only inhibit the reaction by ~50% (Fig. 4); similar results were obtained with *S. aureus* GyrB and 7-methyljuglone (data not shown). For novobiocin, the dependency of rate on inhibitor concentration was sigmoidal, so the data were fitted to a scheme involving the binding of two ligands to the enzyme to achieve inhibition; in the case of dioxytin the data showed a hyperbolic dependence on inhibitor concentration consistent with the binding of one ligand molecule per enzyme to achieve inhibition (Fig. 4). These data suggest that dioxytin is not a competitive inhibitor of the ATPase reaction of GyrB, but that its site of action is likely to be within the GyrB N-terminal domain and can allosterically affect the ATPase reaction (see below).

*The Binding Site of Diospyrin is in GyrB*

The biochemical data presented above suggests that dioxytin can inhibit the topoisomerase reaction of gyrase and that it may act by binding to the GyrB subunit. We used three further approaches to explore this. In previous work we have used limited tryptic digestion to probe ligand-binding sites in gyrase (40-43). Limited digestion of *M. tuberculosis* GyrA with trypsin revealed little or no difference with and without dioxytin (Fig. S3A), whereas differences were observed in the case of GyrB (Fig. S3B). In the case of *E. coli* GyrB43 (the N-terminal domain of GyrB) significant differences in the digestion pattern were also observed with and without dioxytin (Fig. S3C). These data support the idea that dioxytin may bind to the N-terminal domain of GyrB, which houses the ATPase active site (27,44).

Nanoflow-electrospray ionization mass spectrometry (nano-ESI-MS) has been successfully used to analyze the non-covalent interaction between proteins and ligands (45). Recently we have used this method to characterize the interaction between the N-terminal domain of *E. coli* GyrA and the antibiotic simocyclinone D8 (29,31). We have now analyzed the interaction between dioxytin and gyrase by this method (Fig. 5; note that all nano-ESI-MS experiments were performed in the absence of DTT). We found no evidence for interaction between dioxytin and *M. tuberculosis* GyrA (data not shown) but spectra of samples with *M. tuberculosis* GyrB and dioxytin showed additional peaks consistent with a complex between the two (Fig. 5A). In each spectrum two sets of charged species are apparent (indicated by red and yellow circles), which correspond to the GyrB monomer: observed MW = 79,876 +/- 7Da (calculated = 79,263) and a lower molecular weight contaminant, which is likely to be a truncated form of GyrB. In the spectra in the presence of dioxytin, additional species are present (red stars), which correspond to the GyrB monomer with bound ligand: observed MWs = 80,381 +/- 18 Da and 80,320 +/- 6 Da (the MW of dioxytin is 374 Da). *E. coli* GyrB43 shows 3 different charged species the largest of which corresponds to the GyrB43 monomer (observed MW = 43,272 +/- 2 Da (calculated = 43,024); the other two minor species are likely to correspond to protein fragments or contaminants. In the presence of dioxytin a further species (MW 43,313 +/- 10 Da) appears corresponding to the GyrB43 monomer with bound dioxytin (Fig. 5B). No evidence for interaction between dioxytin and the C-terminal domain of *E. coli* GyrB (GyrB47) was found (Fig. S4). Taken together it seems very likely that the binding site for dioxytin lies within the N-terminal domain of GyrB.

To further evaluate the GyrB-dioxytin interaction, surface plasmon resonance (SPR) was employed. Control experiments showed that novobiocin bound to *E. coli* GyrB43 and *M. tuberculosis* GyrB with equilibrium binding constant (K$_D$) values of 10$^{-4}$-10$^{-7}$ M (Fig. S5), consistent with earlier SPR studies on the interaction of this drug with *E. coli* GyrB (46). In experiments with dioxytin, we observed a
specific interaction with *E. coli* GyrB43 (Fig 6), with an upper limit for the $K_d$ determined to be $10^4$ M. Further refinement of this value was impractical due to the tendency of diospyrin to aggregate on the *E. coli* GyrB chip surface at high concentrations (>50 µM; Fig. S5).

From these data it seems very likely that the binding site for diospyrin lies in the N-terminal domain of GyrB, but does not overlap the ATP-binding site. This suggests a mode of interaction that is distinct from that of other known gyrase inhibitors.

**DISCUSSION**

There is a significant and immediate threat from infections due to pathogenic bacteria that is exacerbated by the prevalence of antibiotic-resistant bacteria and diminution in the drug-discovery efforts of large pharma companies (47,48). This means that there is an urgent need for new compounds with antibacterial potential. Plants are a rich and largely untapped source of antibacterials (49-51), although plant extracts have been used medicinally for centuries. For example, the ‘toothbrush tree’ (*Euclea natalensis*) has been traditionally utilized for its medicinal properties by native South Africans, for example the roots are chewed for oral hygiene and for the treatment of bronchitis, pleurisy and chronic asthma (18). Extracts from this plant have been found to show antibacterial activities, particularly against Gram-positive organisms (18), including *M. tuberculosis* (19). Diospyrin isolated from *E. natalensis* was shown to have activity against drug-sensitive and drug-resistant *M. tuberculosis* strains (20). Other naphthoquinones were also tested against *M. tuberculosis* strains and showed the following MIC values (in order of potency): 7-methyljuglone (0.5 µg/mL; 2.6 µM), diospyrin (8 µg/mL; 21.4 µM), isodiospyrin (10 µg/mL; 26.7 µM), neodiospyrin (10 µg/mL; 26.7 µM). However, the *in vivo* target for these compounds is not clear, with 7-methyljuglone having been identified as a subversive substrate for mycothiol disulfide reductase (25), diospyrin found to be an inhibitor of top I from *L. donovani* (23), and isodiospyrin found to be an inhibitor of human top I (24). In an attempt to address this issue, we have tested diospyrin, 7-methyljuglone and other naphthoquinones against gyrase from *M. tuberculosis*, *S. aureus* and *E. coli*.

We have found that diospyrin and other naphthoquinones are inhibitors of the DNA supercoiling reaction of DNA gyrase with IC$_{50}$ values that are comparable with the reported MICs. For example, we found the IC$_{50}$ value for diospyrin against *M. tuberculosis* gyrase to be ~15 µM, which compares to an MIC of ~20 µM (8 µg/mL). Interestingly diospyrin also inhibits the DNA relaxation reaction of gyrase despite our evidence suggesting binding to the ATPase domain of GyrB, which is not required for relaxation activity. Our ATPase experiments suggest that diospyrin is an allosteric inhibitor of this reaction and we propose that it binds to the N-terminal domain of GyrB close to but not overlapping with the ATPase active site. Its mode of action may involve stabilization of a conformation of the N-terminal domain of GyrB that prevents strand passage and thus inhibits both supercoiling and relaxation by gyrase. This mode of action is similar to that proposed by Bender *et al.* (52) for the action of the quinone metabolites of polychlorinated biphenyls on human topo IIα. In the case of the action of naphthoquinones on gyrase, the mechanism would need to involve binding of the inhibitor to the GyrB-NTD in a manner that would prevent strand passage in either direction and not just prevent clamp closure.

The work in this paper provides evidence that gyrase is a target for naphthoquinones. However, we have not proved that it is the primary *in vivo* target in the antibacterial action of these compounds. One way to show this would be to isolate target-based naphthoquinone-resistant mutations and to establish a correlation between potency and target mutations. Our efforts to isolate such mutations in *E. coli* and *M. smegmatis* have so far been unsuccessful. Most gyrase inhibitors found so far either stabilize the DNA cleavage complex by binding to a pocket comprising of residues from GyrA, GyrB and DNA (such as quinolones), or bind to the ATPase site (such as aminocoumarins) (3). Diospyrin does not appear to emulate either of these modes of action but would appear to bind to a novel binding pocket in the N-terminal domain of GyrB, i.e. it has a completely new mode of action.

Given that naphthoquinones and other quinone compounds have been found to inhibit eukaryotic top II, it is interesting to compare their modes of action with that of diospyrin on gyrase. Several naphthoquinones, including juglone, have been shown to inhibit top II and stabilize the cleavage complex (26); these compounds react with thiol groups on the protein. Lindsey *et al.* (33) found that 1,4 benzoquinone is a strong cleavage-complex stimulator and that
the presence of reducing agents led to a reduction in potency, suggesting that that the oxidized form of the compound was the active species. Further, benzoquinone was found to form adducts with Cys residues within the ATPase domain of topo II (Cys 392 and 405 of human topo IIα); mutation of these residues to Ala led to 50% reduction in the potency of the compound (53). More recently Jacob et al. showed that etoposide quinone, a metabolite of etoposide (itself a cleavage-complex inhibitor of topo II (54)), is effective at stabilizing the cleavage complex under non-reducing conditions. Taken together this work suggests that compounds of this class are cleavage-complex-stabilizing inhibitors of eukaryotic topo II that may act via the formation of adducts with Cys residues in the N-terminus (ATPase) domain; although it is unclear as to why mutation of the two key Cys residues in human topo IIα only leads to a ~50% drop in potency.

In comparison, our experiments do not support a similar mode of action. Our results suggest that the naphthoquinone-binding site is within the N-terminal domain of GyrB but as one of the enzymes examined (S. aureus gyrase) lacks Cys residues in the ATPase domain, it is unlikely that covalent adducts with Cys residues form part of the mode of binding. Moreover, in a control experiment, using mass spectrometry, we found no evidence of adduct formation with M. tuberculosis gyrase, and, in particular, the Cys residue in the N-terminal domain is unmodified. In addition, we have also found no evidence of diospyrin and other naphthoquinones stabilizing the gyrase cleavage complex.

A structure of the diospyrin-GyrB complex would clearly be of great value, but, so far, crystallization trials with diospyrin and GyrB and fragments thereof have not yet yielded crystals suitable for diffraction studies. Identification of the naphthoquinone-binding pocket in GyrB would potentiate the development of these compounds as potential anti-TB agents and the design of other molecules that exploit this mode of action.
