Summary: Recently, we reported the spectroscopic and kinetic characterizations of P450 compound I in CYP119A1, effectively closing the catalytic cycle of cytochrome P450 mediated hydroxylations. This mini-review focuses on the developments that made this breakthrough possible. It examines the importance of enzyme purification in the quest for reactive intermediates and reports the preparation of compound I in a second P450 (P450oxy). In an effort to bring clarity to the field, we also examine the validity of controversial reports claiming the production of P450 compound I through the use of peroxynitrite and laser-flash photolysis.

A significant amount of research in the field of bioinorganic chemistry is focused on discerning the intimate details of enzyme catalysis. Critical to these efforts is the preparation of reactive intermediates that form the stations of an enzyme’s catalytic cycle. The study of these transient species is driven by the hope that insights gleaned from their electronic, structural, and kinetic characterizations will guide the design of next generation catalysts or point the way to inhibitors that could serve as drugs for a variety of maladies. Although a thorough characterization of all the intermediates in a catalytic cycle is required for a detailed dissection of the catalytic mechanism, there are certain species that have special significance and, as such, are considered high-value targets for characterization. These species are generally the highly-reactive intermediates that are ultimately responsible for the most important, difficult, or chemically interesting transformation in the catalytic mechanism.

Recently, we reported the capture and characterization of one of the most highly sought intermediates in biological chemistry, P450 compound I (P450-I) (1). This iron(IV)oxo (or ferryl) radical species (7 in Figure 1) had long been thought to be the principal intermediate in P450 catalysis, but due to its highly reactive nature it had eluded definitive characterization for over forty years. The existence of P450-I was postulated based on the observation of a “shunt pathway” (Figure 1), allowing the oxidation of substrates through the use of oxygen donors such as hydrogen peroxide and meta-chloroperbenzoic acid. These oxidants were known to generate high-valent iron-oxo species in heme peroxidases (2,3), suggesting that a similar intermediate might be involved in P450 catalysis. Four decades worth of searching for the elusive P450-I, however, had led to questions not only about its competence as a hydroxylating agent but also its role in P450 catalysis (4-6).

Our investigations confirmed the existence and the reactive nature of the intermediate. P450-I is capable of hydroxylating unactivated C-H bonds with the remarkable rate constant of 1 x 10^7 M^-1 s^-1 (1). Kinetic isotope effects support a mechanism in which P450-I abstracts hydrogen from substrate, forming an iron(IV)hydroxide complex that rapidly recombines with substrate to yield hydroxylated product (7-9 in Figure 1) (1,7,8). An important and perhaps underappreciated consequence of this kinetic result is that it cements the role of compound II (P450-II, 8 in Figure 1) in P450 catalysis: The intermediate is directly involved in substrate oxidation (9,10). In what follows, we highlight the developments that led to the capture and characterization of the elusive P450-I and review insights gained from our electronic and structural characterizations of compounds I and II.

This review also seeks to address recent—and controversial—reports of stable (i.e. relatively unreactive) preparations of P450-I (4,6,11-15). These reports are surprising, given the highly reactive and historically elusive nature of P450-I (1,5). The authors of these studies have argued the need for a new/alternative oxidant in the catalytic cycle. These preparations of unreactive P450-I are reportedly obtained through an unusual process involving the use of peroxynitrite and laser flash photolysis (PN/LFP). We analyze the ability of the PN/LFP method to generate P450-I, hopefully bringing some clarity to the debate.

Closing the Cycle—The Quest for Compound I—

The general paradigm for P450 catalyzed substrate hydroxylations is shown in Figure 1 (16,17). The first step involves the binding of substrate to the resting low-spin ferric enzyme (1). This binding induces structural changes, which often, but not always (16), manifest themselves in the dissociation of the distally coordinated water and the conversion of the heme from low- to high-spin (2). These substrate-induced structural changes facilitate reduction of the ferric enzyme (18), allowing delivery of the first electron to generate the ferrous substrate-bound form of the enzyme (3). Dioxygen then binds to the ferrous heme, forming a species that is best described as ferric superoxide complex (4). The subsequent reduction of this species forms a ferric peroxy species (5), which is protonated at the distal oxygen to generate a ferric hydroperoxo complex (6). The delivery of an additional proton to the distal oxygen cleaves the O-O bond, yielding compound I (7) and a water molecule. Compound I then abstracts hydrogen from substrate to yield compound II (8) and a substrate radical, which rapidly recombine to yield hydroxylated product and ferric enzyme (9). Hydroxylated product then dissociates and water coordinates to the heme to regenerate the resting ferric enzyme (1).

P450-I has not been observed under turnover conditions, but it can be generated transiently via the peroxide shunt using oxidants such as meta-chloroperbenzoic acid (19-21). Traditionally, however, the yields in these experiments have been too low (<5%) to facilitate characterization by more advanced spectroscopic tech-
techniques. As a result, a number of ingenious experiments have been designed in attempts to circumvent the reactive nature of P450-I. These efforts have generally sought to make C-H bond activation (as opposed to compound I formation) rate limiting. It is in this vein, that researchers have employed cryogenic reduction techniques to deliver the reducing equivalent that triggers P450-I formation. In these experiments, the ferrous-oxy form of the enzyme is reduced radiolytically, at cryogenic temperatures, by exposure to $^{60}$Co (22-25), $^{32}$P (26), or synchrotron radiation (27). Reduction of the oxy-complex yields a ferric-peroxo species, which can be annealed at higher temperatures to allow for proton delivery, cleavage of the O-O bond, and P450-I formation. This technique has been coupled with electron nuclear double resonance spectroscopy and x-ray crystallography, in hopes of obtaining electronic and structural characterizations of the intermediate (22-27). These experiments provided clear evidence for cleavage of the dioxygen bond (i.e. the presence of hydroxylated product). However, P450-I did not accumulate to detectable amounts.

Investigators have also sought the use of flash-quench techniques in which a laser pulse triggers the rapid reduction or oxidation of an enzyme’s active-site. The idea with reductive flash-quench (as with cryogenic reduction) is to deliver the electron that triggers compound I formation. The source of electrons in these experiments is a photoactive redox agent that can be attached to the substrate via a hydrocarbon tether or covalently linked through modification of a non-native cysteine. Although electron injection by reductive flash-quench should be fast enough to make C-H bond activation rate limiting, the successful generation of P450-I by this technique has yet to be reported. Instead, researchers have had limited success using the oxidative route. The rapid removal of one electron from the P450 active-site effectively runs the catalytic cycle in reverse, generating compound II (an iron(IV) hydroxide species) from ferric enzyme. As with reductive flash-quench, however, the technique has yet to yield P450-I (28,29).

In efforts to prepare P450-I by slowing the intermediate’s decay, researchers have turned to the use of “slow” substrates. These substrates are compounds that have their targeted H-atoms replaced by fluorines. In theory, this substitution should allow for preparation of the intermediate in high yield, as C-F bonds are not activated by P450-I. However, studies with these fluorinated compounds have found that P450-I either oxidizes alternative (non-fluorinated) positions on the substrate or decays through non-productive uncoupling (30,31).

Amazingly, in spite of these and other intense efforts (32), the capture and characterization of P450-I remained an unobtainable goal in biological chemistry. Indeed, a recent review on the enigmatic nature of P450-I noted that, despite 45 years of effort by the P450 community, the same questions remain: Does P450 compound I exist and how does it oxidize substrates? It was concluded that the quest for the elusive intermediate would require new and improved methods of preparation and detection combined with theoretical simulations (5).

Given this background, what is remarkable about the successful capture of P450-I is that the feat did not require any great advancement in technology. In the end, it did not require “slow” substrates, cryogenic reduction, or the use of flash-quench methods. Likewise, no improvements in rapid mixing or freezing techniques were necessary. The key to our success was simply enzyme purification (1). In what follows, observations that led to the eventual capture and characterization of P450-I will be discussed. In doing so, we hope to draw attention to what may be an underappreciated concern in the quest for reactive intermediates: the presence of endogenous substrates.

The Importance of Enzyme Purification in the Quest for Reactive Intermediates—

In an effort to resolve a debate concerning the UV/Visible spectrum of compound I in CYP119A1 (13,20,33), a P450 from the thermophilic organism Sulfolobus acidocaldarius (34-36), we noticed that the yield of P450-I in stopped-flow reactions was variable. Some enzyme preparations produced no compound I, while others would yield as much as 10%. Importantly, the protein used in these experiments was deemed to be of high purity based not only on its Reinheitzahl value (i.e. R, or purity ratio of $A_{416\text{ nm}}/A_{280\text{ nm}}$) but also an SDS-PAGE gel. Purification was performed according to an established protocol, which involved heat denaturation and ammonium sulfate fractionation followed by size exclusion and ion exchange chromatographies (34).

Although the variable yields of P450-I in stopped-flow experiments were confusing, it seemed possible to justify them in terms of experimental variation/error (e.g. variable equivalents of protein and/or oxidant combined with variable levels of protein activity in different growth batches). A breakthrough came when a buffered solution of “purified” thermophilic enzyme turned cloudy after several days at ~25°C. Centrifugation of this suspension resulted in protein that could generate as much as 40% compound I. This observation suggested that there was a route to increased compound I yields. After careful analysis, it was determined that the enzyme used in our stopped-flow experiments had a mixture of contaminating small molecules bound to its active-site. The presence of these endogenous species hindered compound I formation and expedited its decay.

GC/MS analysis of protein purified according to the established protocol (EP-CYP119A1) revealed that the enzyme contains a distribution of fatty acids (C12, C14, C16, and C18) bound at its active site. Although the binding of these endogenous substrates shows little, if any spectroscopic signature, their presence can strongly (if not completely) suppress compound I formation (Figure 2A). Over 80% of these contaminating fatty acids can be removed through additional ion exchange chromatography (1). The highly purified protein (HP-CYP119A1) obtained from this process shows an ~10-fold increase/decrease in the rate constants for compound I formation/decay, allowing for the preparation of P450-I in high (~75%) yields (Figure 2B). Figure 2C shows that there is very little difference between the UV/Visible spectra of EP- and HP-CYP119A1. Removing the fatty acids from CYP119A1 red-shifts the Soret maximum by ~1 nm.

Preparation of Compound I in a Second P450 (P45023)—

Given our success in preparing compound I in CYP119A1, we looked for another P450 system that might yield the elusive intermediate following extensive purification. We turned to the thermophilic enzyme P45023 (CYP119A2) from Sulfolobus tokodaii. This P450 has 64% sequence identity with CYP119A1 but was reported to have an unusual third Q-band in its visible absorption spectrum (37). We also observed an additional absorption in the Q-band region during the preliminary stages of protein purification (after heat denaturation and ammonium sulfate fractionation). However, this absorption was due to an unknown contaminating species, which was eliminated completely using tangential flow filtration.

Following tangential flow filtration, initial ion exchange chromatography results in P45023 that appears to be of high purity based on SDS-PAGE and its Rz of ~1.65. Yet, P45023 at this stage of purification yields little, if any, compound I (~10% depending on the...
growth batch). As with CYP119A1, GC/MS analysis reveals the presence of a distribution of fatty acids bound to the enzyme. The distribution in P450s is slightly different, predominantly a mixture of C10 and C18. The majority of these endogenous substrates can be removed through an additional chromatographic step (1). This highly purified protein results in enzyme preparations that yield ~65% P450ST-I. In Figure 3, spectra obtained from EPR and Mössbauer measurements on this species are shown in comparison to those obtained for CYP119A1-I.

We note that the observation of endogenous substrates in what might be considered "pure" protein is not unique to the systems reported here. The crystal structures of P450BM3 and P450scc, both contain fatty acids, even though no substrates were added to the purified enzyme (38,39), and similar observations have been made for human microsomal CYP2CA (40). Furthermore, it seems unlikely that this phenomenon is unique to P450s. The rupture of an organism’s cell(s) during the course of enzyme purification releases myriad small molecules, many of them poorly soluble. These species can find refuge in the hydrophobic cavities of enzymes, where they can interfere by blocking substrate access, altering proton transfer pathways, and modifying reduction potentials.

**Compound II: An Underappreciated Partner in C-H Bond Activation**

An important aspect of our work on P450-I is that it confirms that the rebound mechanism is operative in P450-mediated substrate hydroxylations, thereby cementing the role of compound II in C-H bond activation. This means that compound II’s fundamental physical parameters play a role in determining the cleavage of the C-H bond (9,10). To understand this, it is helpful to consider the factors that govern C-H bond activation in this system.

Mayer has written extensively on H-atom abstraction by metal-oxo complexes. Building on the work of Evans, Polanyi, and Bordwell, he has shown that ground state thermodynamics—the energy difference between the C-H bond broken and the O-H bond formed—is generally sufficient to understand reactivity in these systems (41,42). The strength of the O-H bond in compound I and the pKa of compound II, Eq. 1.

\[
\text{D(O-H)} = 23.06 + E_{\text{comp-I}} + 1.37 \cdot pK_a^{\text{comp-II}} + 57.6 = 2 \text{ kcal/mol (1)}
\]

It has been shown that P450’s thiolate ligated heme promotes basic iron(IV)oxo or ferryl species. P450-II is best described as an iron(IV)hydroxide complex, pKa > 8 (10,43-47). Eq. 1 and the elevated pKa observed in P450-II suggest a critical role for P450’s unusual thiolate ligand: to promote C-H bond activation at biologically viable reduction potentials (9,10).

**Peroxynitrite: a Panacea for Compound II Formation?**

Interest in the preparation and characterization of P450-II leads one naturally to peroxynitrite (PN) and the debate surrounding its use in P450s. In 2000, Ullrich and coworkers reported the formation of what appeared to be a ferryl species during the PN-driven inactivation of P450BM3 (48). The PN-generated species, which had a UV/Visible spectrum similar to that of chloroperoxidase compound II (49), was relatively stable, decaying with an apparent rate of 0.08 s^{-1} (half-life ~9 s). These results suggested that PN could be used to prepare P450-II in high-yield, and our group and others sought to use the technique for this purpose. Importantly, however, a thorough spectroscopic characterization of the PN-generated species revealed that it is not a ferryl intermediate (50).

The reaction of PN with P450s generates a ferric nitrosyl complex on the time-scale of stopped-flow and freeze-quench reactions (50). Compound II does not accumulate to an appreciable degree. The Mössbauer, UV/Visible, and resonance Raman spectra of the PN generated intermediate match those of a ferric nitrosyl complex. Importantly, high-field Mössbauer measurements reveal that the PN generated species is S=0, as expected for an {FeNO}^6 complex but inconsistent with an authentic S=1 iron(IV)oxo (or hydroxide) species (50).

**Unreactive Preparations of P450-I: Will the real compound I please stand up?**

We now examine reports of peroxynitrite and laser-flash photolysis being used to generate stable and unreactive preparations of P450-I (4,6,11-15). These reports have led to considerable confusion about the status of compound I and its role in P450 catalysis (51). The idea behind the PN/LFP method was that PN could be reacted with ferric enzyme to generate compound II, which could then be oxidized using laser flash photolysis to yield compound I. The problem with this method is that there is no evidence that the reaction of PN with ferric P450 yields compound II on the time scale of the LFP experiments. As noted above, the reaction of PN with ferric P450 generates a ferric-nitrosyl complex (50). It is not possible to generate compound I from a ferric nitrosyl complex using LFP.

The first report of the PN/LFP method being used to generate P450-I appeared in 2006, when the technique was purportedly used to prepare compound I in CYP119A1 (12). The PN/LFP-generated intermediate was reported to be relatively stable and unreactive towards lauric acid, even under saturating conditions. In a 2008 study, the rate constant for the reaction with lauric acid was revised to 0.8 s^{-1}. It was in this study that proponents of the PN/LFP method first questioned the generally accepted UV/Visible spectrum of P450-I (11). They did so, because their PN/LFP-generated samples lacked a species possessing the well-known spectrum of the intermediate.

The spectrum of P450-I had been previously reported by Ishimura (P450cam) and Siglar (CYP119A1) (19,20). In both cases, the intermediate was generated in low yield by reacting ferric enzyme with m-CPBA, and the spectrum of P450-I was obtained using global analysis techniques. Both P450-I spectra show great similarity to the well-known spectrum of chloroperoxidase compound I (CPO-I) (52), a thiolate-ligated heme protein that has often served as a model system for P450. Importantly, nothing resembling these spectra was produced from the PN/LFP experiments. As a result, proponents of the PN/LFP technique argued that the previously reported P450-I spectra were flawed, suggesting they were obtained through the improper use of global analysis fitting routines. They argued that the results obtained from global analysis techniques are highly dependent upon the initial guess for rate constants and that previous investigators used P450-I decay rates that were too high, because they were biased by knowledge of the CPO-I spectrum (13). Proponents of the PN/LFP technique claimed that the real spectrum of P450-I was almost identical to that of ferric enzyme. Indeed, in a 2009 paper, they wrote: "The UV spectra, and especially the Soret absorbances, of the P450 compounds I are similar to the UV-visible spectra of resting enzymes. This similarity is undoubtedly one of the major difficulties in attempting to detect Compound I under turnover conditions or in reactions of the enzymes with chemical oxidants." (4)

Over the course of 2009, several papers on the ferric-looking P450-I intermediate were published, some even reporting its quantitative production in P450BM3 and CYP119A1 (4,6,14,15). These
species were reported to be reactive but not overly so—oxidizing benzyl alcohol at a rate of $4 \text{ s}^{-1}$ at $22^\circ \text{C}$. The sluggish reactivity of the PN/LFP-generated species led to the call for an alternative oxidant in the catalytic cycle, one that was more oxidizing than the sluggish PN/LFP generated P450-I.

In an effort to provide clarity to the debate, we sought to obtain the UV/Visible spectrum of P450-I from stopped-flow data via model independent methods (33). Singular value decomposition and target testing provided a parameter-free P450-I UV/Visible spectrum that was in excellent agreement with those reported previously by Ishimura and Sligar. Importantly, no assumptions about reaction kinetics were required to obtain the spectrum. The implications are clear. The PN/LFP generated species is not P450-I. This result was confirmed during our most recent investigation of P450-I, where we were able to prepare the intermediate in ~75% yield, obtaining its definitive characterization via Mössbauer, EPR, and UV/Visible spectroscopies (1).

In 2010, a forum in Inorganic Chemistry noted: “What is required is a thorough spectroscopic characterization of the LFP-generated species. Given the reported quantitative yields and exceedingly long lifetimes, the LFP-generated species would seem ripe for spectroscopic characterization, Mössbauer, electron paramagnetic resonance, and resonance Raman spectroscopies, in particular, would provide significant insights into the nature of the LFP generated species. We await these spectroscopic reports.” (33)

To date, no convincing spectroscopic evidence has been presented for the existence of a PN/LFP generated P450-I species. Still, reports of the method’s use continue to appear in the literature, with the most recent report appearing during the writing of this review (53). We briefly examine a troubling (yet insightful) aspect of this recent work. In it, Newcomb and coworkers present the UV/Visible spectrum of the species generated by the PN/LFP method (53). They assign this spectrum to P450-I. To support this claim, they overlay a P450-I reference spectrum, obtained from the reaction of $m$-CPBA with ferric enzyme. Figure 4A shows the data and reference spectrum extracted from Figure 1C of ref. 53. At first glance, it appears that there is good agreement between the P450-I reference spectrum and the spectrum of the PN/LFP generated species, but, upon closer inspection, it is clear that the PN/LFP-generated species lacks Q-band absorbance features that are the hallmarks of P450-I.

The Q-bands are the absorption bands that can be seen in the reference spectrum between ~500-700 nm, but are clearly absent in the raw data (Figure 4A). The most prominent of P450-I’s Q-bands is known to appear at ~690 nm and is thought to be responsible for P450-I’s green color (1,19,20). It is also noteworthy that the 690 nm band cannot be seen in the spectrum shown in Figure 1B of ref. 53, which the authors report can be decomposed into 50% P450-I, 15% P450-II, and 35% ferric enzyme. The lack of a 690 nm band in the raw data of ref. 53 is troubling.

Additionally, the P450-I reference spectrum used in ref. 53 appears to be blue-shifted ~12 nm. To examine the matter further, an analog-to-digital program (54) was used to extract the spectra from Figure 1C of ref. 53. Upon plotting the extracted raw data, one observes that its maximum absorbance is centered at ~355 nm. This is a clear indication that the spectral assignment in ref. 53 is in error. P450-I has a maximum absorbance at ~367 nm (1,19,20,33,52). This can be seen in the Figure 4B, where the data from Figure 1C of ref. 53 are plotted with an actual (unshifted) P450-I spectrum (shown in red) (1). It is clear that the spectrum produced by the PN/LFP method does not belong to P450-I.

In closing the subject, it is interesting to note Newcomb and coworkers use of a shifted P450-I spectrum as their reference and not the ferric-like spectrum that they have argued for previously. One wonders about the implications for their previous work (4,6,11-15). Furthermore, given that the PN/LFP technique does not yield P450-I, it would appear to be difficult to follow P450-I reaction kinetics using this method (4,6,11-15).

**Conclusion and Outlook—**

Enzyme purification is key to the preparation of reactive intermediates. Fatty acids have been found to occupy the active sites of a number of “purified” P450s. In CYP119, the presence of these small molecules hinders the formation and expedites the decay of compound I. Removal of these endogenous substrates through extensive enzyme purification allows for the preparation of P450-I in high yield. Importantly, P450-I prepared in this manner can be reacted directly with substrate, allowing researchers to avoid the limitations of steady-state kinetics. The use of transient techniques has the potential to provide unprecedented insight into a number of P450 mediated oxidations. The subset of P450s that is amenable to this treatment, however, is unknown. Significant effort has only been devoted towards the thermophilic enzymes discussed here.

Finally, consider that this is not the first time that endogenous reductants have masked or interfered with the formation of high-valent intermediates in heme systems. Indeed, the first intermediate identified in the reaction of horseradish peroxidase with hydrogen peroxide was compound II (55). It was not until four years later, in 1941, that the observation of compound I was reported (55). In 1976, Dunford and Stillman wrote: “Work on all peroxidases has been hampered by the spontaneous decay of both compound I and compound II, particularly the former, a problem which can be circumvented today only by careful work on pure enzyme samples.” (55) Given this history and the observation of bound substrates in the crystal structures of “purified” P450s, it is interesting to think that the stage was set for the isolation of P450-I at least a decade ago. Hindsight is always 20/20.

FIGURE LEGENDS

Figure 1. The general paradigm for P450 catalyzed hydroxylations. The first step involves the binding of substrate to the resting low-spin ferric enzyme (1). This binding induces structural changes, which often, but not always, manifest themselves in the dissociation of the distally coordinated water and the conversion of the heme from low- to high-spin (2). These substrate-induced structural changes facilitate reduction of the ferric enzyme, allowing delivery of the first electron to generate the ferrous substrate-bound form of the enzyme (3). Dioxygen then binds to the ferrous heme, forming a species that is best described as a ferric superoxide complex (4). The subsequent reduction of this species forms a ferric peroxo species (5), which is protonated at the distal oxygen to generate a ferric hydroperoxo complex (6). The delivery of an additional proton to the distal oxygen cleaves the O-O bond, yielding compound I (7) and a water molecule. Compound I then abstracts hydrogen from substrate to yield compound II (8) and a substrate radical, which rapidly recombine to yield hydroxylated product and ferric enzyme (9). Hydroxylated product then dissociates and water coordinates to the heme to regenerate the resting ferric enzyme (1).

(A) Spectrum of EP-CYP119A1 (black) and a spectrum taken (at maximum formation of P450-I) during the reaction of EP-CYP119A1 with two equivalents of m-CPBA at 4°C (blue). Compound I is formed in very low yield. (B) Spectrum of HP-CYP119A1 (black) and a spectrum taken (at maximum formation of P450-I) during the reaction of HP-CYP119A1 with two equivalents of m-CPBA at 4°C (blue). Compound I can be produced in up to ~75% yield. (C) Overlay of HP (red) and EP (black) CYP119A1.

Figure 3. Comparison of the EPR (left) and Mössbauer (right) spectra of CYP119A1-I and P450ST-I. Mössbauer spectra were recorded at 4.2K with a 54mT field oriented parallel to the γ–beam. Mössbauer spectra were obtained by subtracting contributions of ferric enzyme (30 and 35% respectively) from the raw data. Fits of the Mössbauer data (shown in red) yield the following parameters: P450ST-I (ΔEQ = 0.85 mm/s, δ =0.12 mm/s), CYP119A1-I (ΔEQ = 0.90 mm/s, δ =0.11 mm/s). The EPR spectra were obtained as reported previously (1). Fits of the P450ST-I EPR data indicate |J/D| = 1.3 and g =(1.95, 1.84, 1.99), in good agreement with the values reported previously for CYP119A1-I (1).
