Keywords: Ankyrin-G; Na, channel; KCNQ channel; AIS; convergent evolution

Background: Neuronal axons use dense clusters of voltage-gated ion channels to conduct rapid electrical signals called action potentials.

Results: We mapped sites on a cytoskeleton protein, ankyrin-G, which bind and cluster sodium and potassium channels.

Conclusion: Channel binding is dually regulated by casein kinase phosphorylation and the ankyrin-G sequence.

Significance: The new mechanisms identified control axonal membrane excitability and are drug development candidates.

ABSTRACT

In many mammalian neurons, fidelity and robustness of action potential generation and conduction depends on the co-localization of voltage-gated sodium (Na,) and KCNQ2/3 potassium channel conductances at the distal axon initial segment (AIS) and nodes of Ranvier (NR) in a ratio of approximately 40 to 1. Analogous “anchor” peptides within intracellular domains of vertebrate KCNQ2, KCNQ3 and Na, channel α-subunits bind Ankyrin-G (AnkG), thereby mediating concentration of those channels at AISs and NRs. Here, we show that the channel anchors bind at overlapping but distinct sites near the AnkG N-terminus. In pull down assays, the rank order of AnkG binding strength is Na,1.2>>KCNQ3>KCNQ2. Phosphorylation of KCNQ2 and KCNQ3 anchor domains by casein kinase 2 (CK2) augments binding, as previously shown for Na,1.2. An AnkG fragment comprising ankyrin repeats 1 through 7 (R1-7) binds phosphorylated Na, or KCNQ anchors robustly. However, mutational analysis of R1-7 reveals differences in binding mechanisms. A smaller fragment, R1-6, exhibits much-diminished KCNQ3 binding but binds Na,1.2 well. Two lysine residues at the tip of repeat 2-3 β-hairpin (residues 105-106) are critical for Na,1.2 but not KCNQ3 channel binding. Another dibasic motif (residues R47, R50) in the first repeat 1 α-helix is crucial for KCNQ2/3 but not Na,1.2 binding. AnkG’s alternatively spliced N-terminus selectively gates access to those sites, blocking KCNQ but not Na, channel binding. These findings suggest that the 40:1 Na,,:KCNQ channel conductance ratio at the distal AIS and nodes arises from the relative strength of binding to AnkG.
Differential Na\textsubscript{v} and KCNQ2/3 channel binding to Ankyrin-G

generation at the axon initial segment (AIS) and conduction at nodes of Ranvier (NR) (2-5). Na\textsubscript{v} channels (including Na\textsubscript{v}1.1, 1.2, and 1.6 \(\alpha\)-subunits, depending on cell type) and KCNQ channels (either KCNQ2/KCNQ3 heteromers, or KCNQ2 homomers) are concentrated at AISs and nodes of Ranvier by interaction of their intracellular domains with a scaffolding protein AnkG (Fig. 1). AnkG not only plays a central role in establishing and maintaining the specialized electrical activity of AISs and nodes, but is essential for neuronal axodendritic polarity (6-10). AnkG is a very large molecule with diverse splice isoforms (190-480 kDa; see schematic structure, Fig. 1C) known to be capable of recognizing many ligands including Na\textsubscript{v} and KCNQ2/3 channels via its membrane binding (MB) domain (6,11,12). The MB domain consists of 24 ankyrin repeats encoded by 22 exons. A canonical ankyrin repeat contains 33 amino acid residues. Ankyrin repeat structures have been extensively studied (13,14).

Understanding the mechanisms determining the clustering of AIS and nodal channels is of both biological and medical interest. The protein complex of AnkG and its axonal channel ligands is implicated in psychiatric and neurological diseases. Variation in ANK3, the gene encoding AnkG, is strongly associated with bipolar disorder, and Na\textsubscript{v} blocking drugs are very commonly used as mood stabilizers (15). Mutations in genes for both Na\textsubscript{v} and KCNQ2 channels cause severe forms of epilepsy associated with developmental impairment and autism (16-19). Studies combining pharmacology, electrophysiology, and computational modeling suggest that relatively minor changes in the ratio of AIS KCNQ and Na\textsubscript{v} conductance can have a large impact on neuronal responsiveness (5,20,21).

What is the role of AnkG in setting the number and ratio of AIS and nodal channels? Previously Pan et al. identified a highly conserved \(\sim 80\) amino acid ankyrin-binding domain at the distal end of the intracellular C-terminus of KCNQ2 and KCNQ3 (3). Within this larger domain, a 9 amino acid segment mimics the Na\textsubscript{v} channel ankyrin-G binding sequence (3,22,23). Hill et al. found that, although the Na\textsubscript{v} and KCNQ channel anchor sequences for binding ankyrin-G are similar, the Na\textsubscript{v} sequence appeared 50-100 million years earlier during vertebrate evolution (24). This sequence similarity suggests that Na\textsubscript{v} and KCNQ channels might bind at similar or identical locations on the AnkG polypeptide. Here we characterize AnkG association with Na\textsubscript{v} and KCNQ2/3 channels; our results show that both Na\textsubscript{v} and KCNQ2/3 channel preferentially binds to an overlapped area on AnkG within the first seven ankyrin repeats. However, Na\textsubscript{v} channels bind much more tightly to AnkG than KCNQ2/3 channels. Although Na\textsubscript{v} and KCNQ2/3 channel share a binding region, different residues are critical for binding. Furthermore, the AnkG N-terminus selectively interfere with KCNQ2/3 interaction but has no effect on Na\textsubscript{v} channel interaction. We argue that these results indicate that AnkG recruits membrane Na\textsubscript{v} and KCNQ channels and maintains precisely the Na\textsubscript{v} : KCNQ ratio via 1) differential binding of the channel ligands and 2) N-terminus regulation, thus underlying normal neuronal excitability.

**EXPERIMENTAL PROCEDURES**

**Reagents—**Rabbit anti-AnkG (NT3, for “N-terminus 3”) was raised against the synthetic peptide “AHAASQLKKNRDLEINAEEEC”, corresponding to an alternatively used 5’ coding exon (exon 1b, Zhou et al, 1998) of Ankyrin-G. Antibodies were affinity-purified against the immunogens (SulfoLink, Pierce) before use. Other antibodies were purchased: mouse anti-GFP (Neuromabs), rabbit anti-GFP (Invitrogen), rat monoclonal (Roche, Basel, Switzerland). Secondary antibodies, highly purified to minimize cross-reactivity, were from Jackson ImmunoResearch (West Grove, PA). A cDNA encoding the 270 kD isoform of rat ankyrin-G was obtained from Vann Bennett (25).  Cloned human KCNQ2 and KCNQ3 cDNAs were obtained from Thomas Jentsch (26,27).

cDNA constructs—AnkG-MB-GFP, KCNQ2-Neurofascin-HA and CD4-Na\textsubscript{v}II-III constructs have been described previously (3,22). Constructs encoding various fragments of the AnkG-MB domain were generated by PCR with \textit{pfu} polymerase. Those PCR products were inserted into EcoRI and SalI sites of pEGFP-N1 (Invitrogen). GST-Na\textsubscript{v}1.2 DII-III loop was generated by PCR amplification using the rat Na\textsubscript{v}1.2 cDNA clone (28) as template. The PCR product, corresponding to residues 989-1203 of the domain DII-III intracellular loop, was inserted
into BamHI+SaiI sites of pGEX4T-1. The distal portion of the C-terminal intracellular domains of human KCNQ2 and KCNQ3 were cloned into BamHI+NotI sites of pGEX6p-1 to make GST-Q2C (571-844) and GST-Q3C (578-872). To generate clones encoding alternatively used AnkG N-termini NT1 and NT2, we exploited a unique PstI site within the first repeat (R1) of the rat AnkG cDNA. We synthesized cDNAs for NT1-R1 or NT2-R1, including a BamHI site at 5’ end and cloned this fragment into pUC57 (Genewiz). The NT1-R1, NT2-R1 fragments were digested out with BamHI and PstI, and inserted into pEGFP-AnkG N-R7 digested with BamHI and PstI.

Deletion and alanine substitution mutations in AnkG were made using Quickchange (Stratagene) using rat AnkG-NT3 cDNA as template. The β hairpin tip alanine mutations were introduced at positions corresponding to the first and last codon of exons, i.e., hairpin 1 H1: 39,40SD-AA; H2: 71,72NQ-AA; H3: 105,106KK-AA; H4: 138,139QN-AA; H5: 171,172ED-AA; H6: 204,205PA-AA; H7: 241,242ES-AA. The alanine substitution mutations within the AnkG-NT3 non-ankyrin N-terminus were at MBN-R7KKKK24-27, RKR29-31, KKK36-38, EEETE19-23, E15+EEETE19-23. Other alanine substitution mutations were R47, R50 in repeat 1. To mimic AnkG splice isoforms lacking exon 7(29), codons 234-241 encoding residues MVVNRATE were deleted.

All constructs were verified by DNA sequencing before use. Additional cloning details are provided in supplemental Table S1.

Fusion protein expression and purification—GST fusion proteins were expressed in Escherichia coli strain BL21 (DE3) and induced by 1 mM Isopropyl β-D-1-thiogalactopyranoside (IPTG). Overexpressed GST fusion proteins were affinity-purified by glutathione-sepharose 4B according to the manufacturer’s manual (GE Healthcare). The protein eluted was dialyzed against 1L phosphate-buffered saline (PBS, diluted from 10X PBS, Thermo Scientific) using 10kD MWCO dialysis cassettes (Pierce). Protein concentration was estimated by colloidal coomassie blue staining (Invitrogen), using a standard curve generated using bovine serum albumin (BSA). Purified proteins were aliquoted and snap-frozen in liquid nitrogen and stored (-80° C).

In-vitro Casein Kinase (CK2) phosphorylation—Phosphorylation reactions were performed by incubating purified GST fusion proteins (2 μg) with 1x CK2 buffer containing 200 μM ATP and 10 units of CK2 (NEB) for 1hr at 30° C. For the control conditions, protein samples were treated identically except CK2 was omitted.

Cell culture and transfection—Human embryonic kidney (HEK) 293 cells were cultured in MEM medium containing 10% fetal bovine serum (Invitrogen). X-tremeGENE 9 (Roche) or Lipofectamine 2000 (Invitrogen) were used for transfection following the manufacturer’s manual.

Surface redistribution assay and immunostaining—The AnkG surface redistribution screening assay (Fig. 4) has been previously described (3,25,30). In brief, HEK293 cells were transfected with plasmids AnkG-MB GFP together and HA-tagged NF-KCNQ2 C terminal (residues 571-844) plasmids, and replated onto coverslips at low density. Cells were fixed 2 days after transfection. After washing 3 times, the cells were blocked in 10% normal goat serum, 2% BSA, 1xPBS for 1 hr, then incubated with rat anti-HA antibody at 4° C overnight. Cells were washed 5 times with PBS then incubated with Cy3-conjugated anti rat IgG antibody for 2 hrs at room temperature. Coverslips were mounted using Prolong Gold (Invitrogen), and photographed at high magnification (60X) under epifluorescence. Cells included in groups photographed and analyzed further fulfilled several criteria. They were well-isolated, and spindle shaped or multipolar. Small cells lacking a clearly defined cytoplasmic compartment were excluded. Under red immunofluorescence, cells that gave anti-HA-positive staining with a clearly resolved edge distribution were photographed, and then the distribution of green fluorescence was analyzed. For each experimental condition, images of 20 or more cells from three separate transfection experiments were collected. Imaged cells were classified as either possessing (edge positive) or lacking (edge negative) an easily detected green fluorescence surface “edge” that co-localized with the red anti-HA staining. Intensity histogram line positions were chosen so they would cross positions where the red HA surface edge and
underlying cytoplasmic compartment were readily detected.

Cellular localization correlation analysis—To analyze KCNQ2/3 and Na, interaction with AnkG in a cellular environment, we used a localization correlation approach (31-33). NF-Q2C or CD4-Na,II-III constructs were co-transfected in HEK293 cells with GFP-fused AnkG MB fragments. Two day after transfection, cells were fixed, washed 3 times, permeabilized with 1xPBS containing 0.2% Triton X-100 (TX-100); blocked in 10% normal goat serum, 2% BSA, 1xPBS, 0.02% TX-100 for 1 hr, then incubated with rat anti-HA antibody at 4° C overnight. Cells were washed 5 times with PBS with 0.02% TX-100, then incubated with Cy3-conjugated anti rat IgG antibody for 2 hrs at room temperature, then mounted and imaged. Images for analysis were acquired from 3 independent transfections. The co-localization of red and green fluorescence was quantified using NIS Elements AR (Nikon Instruments.) Define ROI selected: based on overlapped/merged green and red channel

CK2 activity inhibition–TBB and TBCA (4,5,6,7-Tetrabromo-2-azabenzimidazole, and ((E)-3-(2,3,4,5-Tetrabromophenyl)acrylic acid, Sigma) were used as CK2 inhibitors. TBB was dissolved in DMSO at 10 mM; TBCA was dissolved in DMSO at 5mM. HEK293 cells were co-transfected with MB-GFP and NF-Q2C. One day after transfection, 50 μM TBB or 25 μM TBCA was added to culture medium for either 6 hours or 24 hours. DMSO alone was added to controls.

Image acquisition and analysis–Epifluorescence images were collected using a Nikon 80i microscope, a 60x, 1.4 numerical aperture Plan Apo oil immersion objective, and an Exi Aqua CCD camera (QiImaging) driven by NIS Elements (Nikon) software.

Sequential pull down and western blot – For each condition, equal amounts (2 μg) of purified GST fusion proteins either phosphorylated or non-phosphorylated by CK2 were incubated with glutathione beads for 2 hours at 4° C. After extensive washing, GST fusion protein coated beads were further incubated with cell lysate from HEK cell expressed various AnkG-MB domain truncations fused with GFP, then, after another extensively wash, the pull down protein complex were eluted using Laemmli sample buffer (2X) with DTT for 5 min at 95° C. The samples were resolved in SDS-PAGE and transferred to nitrocellulose membranes (Bio-Rad), then subject to western blot and enhance chemiluminescent detection using the ECL kit (GE Healthcare).

RESULTS

Phosphorylation by casein kinase 2 (CK2) enhances KCNQ2 and KCNQ3 association with AnkG–Although expressed ubiquitously, CK2 is enriched at AISs and nodes of Ranvier (34). Four conserved CK2 consensus sites lie within or immediately C-terminal to the Na, channel anchor motif; phosphorylation of these sites has been shown to markedly enhance binding of AnkG (34,35). Although Na, and KCNQ2/3 sequences have low similarity outside of the short anchor motifs (Fig. 2A, red asterisks), the C-terminal intracellular domains of KCNQ2 and KCNQ3 nonetheless have, respectively, 3 and 4 consensus CK2 sites in or C-terminal to their anchor motifs (Fig. 1A, arrows). To determine if CK2-mediated phosphorylation regulates KCNQ2/3 binding of AnkG, we performed sequential in vitro CK2 phosphorylation and pull down experiments using GST-fused channel baits and soluble, heterologously-expressed AnkG prey. The Na,1.2 bait included the entire intracellular loop between homology domains II and III (shown in red in Fig. 1A, (34)); the KCNQ2/3 baits extended from the tetramerization domain tail (36) to the C-terminus (KCNQ2 residues 571-844, KCNQ3 residues 578-872, red in Fig. 1B). Purified baits (GST-Q2C, GST-Q3C, GST-Na,II-III or GST) were incubated with purified CK2 and ATP; in controls, CK2 was omitted. After 30 minutes, CK2 treated and control fusion proteins were collected on glutathione beads, washed extensively, and then mixed with lysates of HEK cells expressing AnkG membrane-binding domain green fluorescence protein fusion proteins (AnkG-MB-GFP). Western blots showed that, without CK2 phosphorylation, KCNQ2 and KCNQ3 baits pulled down AnkG-MB-GFP very weakly but detectably, whereas unphosphorylated Na, bait yielded a much greater signal (Fig.2B). For all the channel fusion baits, but not GST, CK2 phosphorylation markedly enhanced binding of AnkG-MB-GFP.

CK2 inhibitor treatment decreases co-localization of MB-GFP and NF-Q2C–The
selective CK2 inhibitors TBB and TBCA have been used previously to study CK2 effects on \( \text{Na}_v \) channel localization and KCNQ2 channel function (34,37,38). To further analyze the role of CK2 in regulation of AnkG and KCNQ channel interactions, we treated HEK cells expressing AnkG MB and either \( \text{Na}_v \) or KCNQ anchor-bearing fusion constructs. Six hr treatment with TBCA, but not TBB, induced a significant reduction of co-localization of NF-Q2C and AnkG compared to treated vehicle controls (Fig. 3 A-C, G). After 24 hr exposure to either TBB or TBCA, co-localization was significantly reduced (Fig. 3D-G). These results indicate that CK2 activity inhibition alters interaction between the KCNQ2 and AnkG MB in intact HEK293 cells.

An AnkG-MB fragment (N-R12, ~400 residues) contains the KCNQ2 binding site–Previously, Pan et al. used AnkG-MB-GFP as a reporter in a cell-based surface redistribution assay to identify the homologous KCNQ2/KCNQ3 anchor motifs (3,30). We generated expression constructs including 3 overlapping fragments of the AnkG-MB domain (Fig. 4A), and compared their ability to be concentrated at the cell membrane by interaction with the KCNQ2C polypeptide (residues 571-844, Fig. 1B). In 21 of 21 cells studied, AnkG-MB-GFP, containing the non-ankyrin repeat N-terminus and all 24 ankyrin repeats, was efficiently redistributed to the cell membrane (Fig. 4B), as was an N-R12 truncation construct (32/33 cells studied, Fig. 4C). MB (R11-17) and MB (R16-24) constructs remained homogeneously distributed in the cytoplasm, and never showed an “edge” appearance (0/27 and 0/22 cells, respectively; Fig. 4D-E). We were unable to achieve efficient cytoplasmic expression of smaller AnkG N-termin al constructs (data not shown). Alternatively, we performed pull down experiments using CK2-phosphorylated GST-Q3C and GST–\( \text{Na}_v \) II-III fusion proteins baits and overlapping AnkG-MB fragments as prey. Although the \( \text{Na}_v \) and KCNQ3 baits showed detectable CK2 phosphorylation-dependent binding of N-R17 and R7-R24 fragments, binding of the N-R17 fragment was much stronger (Fig. 5A-B).

An N-R6 AnkG fragment is sufficient for robust binding to the \( \text{Na}_v \) anchor, but a larger N-R7 fragment is required for robust binding to KCNQ3–To further map channel binding sites within the AnkG-MB, we performed additional pull down experiments using smaller MB fragments as prey (Fig. 5). In a series of C-terminal truncations at exon-exon junctions, AnkG-MB N-R7 was the minimal fragment sufficient to bind the CK2-phosphorylated KCNQ3 anchor robustly (Fig. 5C, D). A smaller fragment, N-R6, bound the \( \text{Na}_v \) anchor well, but bound the KCNQ3 anchor much more poorly (Fig. 5C).

Exon 7 in vertebrate ankyrins is atypical, only 8 codons in length, and analysis of brain and heart tissues indicate it is alternatively spliced (29), (data not shown). As a result, the R6-7 \( \beta \)-hairpin has alternative forms possessing and lacking an 8 amino acid insert (termed here, R6L and R6S). Deletion of exon 7 had no effect on binding to either channel (Fig. 5D). Repeats 5 and 6 are coded on the same exon (exon 6 in vertebrates, Fig. 5E), and are the only repeats that break the canonical 33 residue per repeat pattern (39) and structure (14,40); see discussion). Deletion of exon 6/R5-6 resulted in an N-R4 fragment that showed markedly reduced binding to either anchor (Fig. 5D). Likewise, a deletion eliminating the non-ankyrin-repeat N-terminus and R1 abolished binding to either channel (Fig. 5D).

The third AnkG \( \beta \)-hairpin tip is required for robust binding to \( \text{Na}_v \) but not KCNQ2/3–The above findings indicate that the main site for recognizing both channels was within the N-R7 region. While N-R7 is a small portion of the whole AnkG polypeptide, it still offers a large potential binding surface. To further elucidate differences in \( \text{Na}_v \) and KCNQ2/3 anchor binding, we used a combination of scanning and targeted point mutagenesis. The \( \beta \)-hairpin tips of ankyrin repeats are relatively variable in sequence and exposed to ligands, and therefore often contribute to sites of specific binding. In AnkG, these tips are of additional interest since they correspond to exon-exon junction sites and are thus may confer distinctive ligand binding through alternative splicing (13,14,29,41). We therefore tested a series of mutant N-R7 constructs in which predicted \( \beta \)-hairpin tips were individually substituted by di-alanine mutations (Fig. 6A-C). Pull down experiments with CK2-phosphorylated GST-\( \text{Na}_v \) II-III and GST-Q3C showed that mutation of \( \beta \)-hairpin 3 (H3), between repeats R2 and R3, exhibited dramatic loss of binding to \( \text{Na}_v \) II-III.
The disrupted Na, II-III binding was observable by both western blot and Ponceau staining (Fig. 6C, black arrow). Binding to phosphorylated KCNQ3-C was unchanged by mutation of H3. Mutation at other β-hairpin tips had no effect on binding to either channel type. The H3 tip consists of two lysines (indicated in red, Fig. 6A, E, F) whereas anchor sequences of Na, and KCNQ2/3 channels possess multiple acidic and phosphorylated side chains. This suggests that electrostatic interactions involving this tip may be essential for binding of Na, channels to AnkG.

When introduced into full-length (N-R24) AnkG-MB, the H3 di-alanine mutation had no effect on binding to GST-Na, II-III (data not shown). We hypothesized that, since earlier experiments showed evidence of weak interaction with R7-24, change restricted to this hairpin tip might be compensated by other contributions from other sites, or even by (physiologically irrelevant) simultaneous interactions with multiple bait molecules. We therefore introduced a larger disruption including H3, namely removal of R2-R3 with fusion of R1 and R4 at a potential native exon-exon junction site (Fig. 6F). The R2-R3 deletion decreased binding to GST-Na, II-III markedly, but had little effect on binding to GST-KCNQ3C (Fig. 6E, lanes 1-3, 6F).

A dibasic sequence in repeat 1 contributes to KCNQ2/3 but not Na, channel binding–MB N-R12 binds to both channel types, while MB R2-12 binds neither (Fig. 5D). To identify sites within the N-R1 region critical for binding Na, or KCNQ channels, we made additional alanine mutations, focusing on charged residues that might also interact electrostatically with the anchor domains. Previously, Abdi et al. obtained evidence for interaction between an acidic sequence in the C-terminal of ankyrin-B (amino acids 1597-1599, EED) and a basic sequence, RAAR, located in the front α-helix of ankyrin repeat 1 of Ankyrin B (42). This RAAR sequence is conserved in vertebrate and protostome ankyrins (data not shown). We noted that the ankyrin-B C-terminal ligand sequence, EED, resembles the key residues of the anchor motifs (ESD for KCNQ2 and Na, and ETD for KCNQ3), especially if the S and T residues are phosphorylated by CK2 (34,43). Therefore, we generated R47A, R50A mutated AnkG N-R7 (Fig. 6A, 7A) and performed pull down assays. R47A, R50A mutation caused the complete loss of KCNQ2 and KCNQ3 binding activity (Fig. 7B-C, lanes a-b), but had no detectable effect on Na, channel binding (Fig. 7B).

The initial N-terminal portion of all ankyrins consists of a non-ankyrin sequence encoded by one or two exons. The clone used here, and in many previous studies by us and others (3,25,44) has a 39 residue N-terminal bearing 3 clusters of basic amino acids and one cluster of acidic amino acids (Fig. 7A). We made alanine substitution mutations for several combinations of positive charged residues: KKKK24-27; RKR29-31; KKK36-38 and acidic residues: E15, EEE19-21, and EEETE19-23. None of these mutant constructs changed the binding to either KCNQ3 or Na, baits (Fig. 7D-F).

To further assess the role of the repeat 1 R47, R50 residues in a cellular context, we introduced R47A, R50A mutations into GFP-tagged AnkG MB and MB Ndel, and assayed co-localization with HA-tagged NF-Q2C in intact HEK293 cells (Fig. 8). Rows A-G show GFP and HA fluorescence of representative cells that gave correlation values near the means plotted in panel H. As expected, GFP and NF-Q2C localization was poorly correlated, whereas AnkG MB, MB Ndel, or R1-7 localization was highly correlated with NF-Q2C. Interestingly, whereas AnkG MB was redistributed to the cell surface when co-expressed with NF-Q2C (Fig. 8A-B), the N-terminus-lacking fragments most effective in pull down assays caused NF-Q2C to be redistributed intracellularly (Fig. 8C and F). R47A, R50A mutated MB Ndel (Fig. 8E) or R1-7 (Fig. 8G) diminished the intracellular staining for NF-Q2C, and significantly reduced localization correlation: (P<0.001 and P<0.01 respectively, Fig. 8H). R47A, R50A mutation gave no significant effect on co-localization of AnkG MB and NF-Q2C, suggesting that the presence of the N-terminal may weaken the impact of 47, 50 mutation.

The non-ankyrin repeat N-terminus of AnkG inhibits KCNQ2/3 but not Na, channel binding–As targeted mutation of charged residues in the N-terminus failed to mimic the effect of deleting N-R1, we generated a construct deleting all 39 residues of the N-terminal. Surprisingly, this construct, R1-7, exhibited remarkably enhanced binding to both GST-Q3C (Fig. 7A) and GST-Q2C (Fig. 7B), compared to N-R7. Binding enhancement by removal of the N-terminus was
robust, even without phosphorylation of the Q2C bait by CK2 (Fig. 7C). By contrast, N-R7 and R1-7 constructs bound to the Na, channel bait equally well. The selective importance of the R1 dibasic site (R47, 50) for KCNQ2/3 binding was further underlined by introduction of alanine substitutions of those residues into R1-7 (Fig. 7B-C, lanes c-d). The double mutation very strongly reduced KCNQ2/3 binding to R1-7, but had no effect on Na, binding.

To examine the contribution of the N-terminus to binding in larger context, we introduced the deletion into full-length AnkG-MB and performed pull down experiments. Consistent with results using the R1-7 fragment, the deletion increased binding to the KCNQ3 channel but not to the Na, bait (Fig. 6E-F).

ANK3 alternative N-termini differentially regulate KCNQ2/3 and Na, channel association with AnkG—ANK3 has at least three alternative promoters and corresponding first exons encoding non-ankyrin N-termini variants (namely exon1a, exon1e, and exon1b, encoding NT1-3, respectively; Fig. 9A, B) (6,42,45,46). These promoters and alternative N-termini exhibit tissue and cell type specific expression. Exons 1b and 1e are expressed in central neurons, whereas NT1 is expressed in other tissues (6,42). Our experiments all used the widely distributed NT3-bearing clone of rat AnkG (6). We therefore examined whether NT1 and NT2, like NT3, were able to inhibit KCNQ channel binding to AnkG. NT1, NT2, and NT-3 are 33, 21 39 amino acids in length, respectively (Fig. 9A). We performed pull down assays in parallel using 3 identical constructs except for the N-termini (Fig. 9C). Whereas both NT2 and NT3 strongly inhibited AnkG association with the KCNQ3 bait, NT1 slightly inhibited binding. The 3 N-termini had no effect on Na, channel binding. KCNQ2 and KCNQ3 are relatively new genes, arising first by gene duplications in an ancestor of the jawed vertebrates (24). Interestingly, the AnkG N-terminal sequences are also jawed vertebrate novelties absent from invertebrates (46); within gnathostomes, they are extremely well conserved, as illustrated by alignment of the NT3 residues of Danio rerio and Homo sapiens (Fig. 9A). We attempted to measure interaction between GST fused with the AnkG NT3 N-terminus and the soluble R1-7-GFP fragment by similar pull down assays, but no binding was detectable (data not shown).

These results imply that the non-ankyrin repeat N-terminus can differentially regulate cargo binding activity of the adjoining ankyrin repeats. The N-terminus selectively interferes with KCNQ3/2 channel but not Na, channel binding to AnkG. On the basis of our findings, we propose a “gated binding pocket” model for AnkG N-R7 interaction with Na, and KCNQ2/3 channel proteins (Fig. 10). Secondary structure prediction algorithms indicate that the N-terminus is primarily α-helical (47,48). The R1-7 repeats provide the binding surface recognized by both channels. The non-ankyrin repeat N-terminus restricts access to the pocket, leaving it sufficiently open to be entered by the Na, channel’s smaller anchor (Fig. 10C), but far less easily by the KCNQ2/3 anchor (Fig. 10D), thus, leads to lower affinity. Removal of the N-terminus, achieved experimentally by deletion, but perhaps by conformational change and as yet unknown regulatory mechanisms in vivo, increases KCNQ2/3 anchor access, without effect on Na, channel access (Fig. 10E).

DISCUSSION

Mammalian axons have evolved signaling systems that are reliable, fast-conducting, spatially compact, and energetically efficient (7,24,49,50). This is achieved through genetic and developmental programs enabling protein deployment along the axon that is modular and elaborately polarized, radially and longitudinally. Recent studies have highlighted the central roles played by all three vertebrate ankyrins (ankyrin-G, -B, and -R) in axonal development, structure and excitability (10,44,51,52). Here we investigate AnkG biochemical interactions needed for the concentration of membrane voltage-gated sodium and KCNQ2/3 ion channels at initial segments and nodes of Ranvier. We mapped the binding sites within AnkG for KCNQ2/3 and Na,1.2 and characterized molecular determinants for these interactions.

First, we found that CK2 phosphorylation markedly enhanced the ability of KCNQ2/3 C-terminal anchor domains to bind AnkG. Moreover, inhibition of CK2 activity diminished the colocalization of transfected AnkG and NF-Q2 fusion proteins co-expressed in HEK293 cells.
CK2 has been shown to be enriched at the AIS, to regulate activity of KCNQ2 through phosphorylation of bound calmodulin, and to phosphorylate Na_v channels and thereby enhance their binding to AnkG (34,35,37,53,54). Together, the new findings further support a “lock in place” mechanism where, after being synthesized in the soma or dendrites, Na_v and KCNQ2/3 channels are transported to the axon hillock, admitted to the AIS, and phosphorylated at their anchor domains by local CK2. Once phosphorylated, and captured within the diffusion barrier of the AIS/nodal membrane near abundant AnkG (55), exit from the AIS would be slowed, even if the dimeric interaction between the ligand and AnkG was relatively weak. This appears to be the case for KCNQ2/3 channels: even under our in vitro conditions, binding is very sub-stoichiometric (unlike Na_v; Fig. 6C-D). Also, though overexpressed NF-Q2C fusion proteins redistribute AnkG to the membrane efficiently (Fig. 2), the association is completely lost during immunoprecipitation experiments from HEK lysates (data not shown). Indeed, with or without phosphorylation by CK2, Na_v.1.2 binds to AnkG much more strongly than KCNQ3 and KCNQ2 do. The ratio of Na_v and KCNQ peak conductance measured by voltage-clamp at rat sciatic nerve nodes of Ranvier (56) and L5 cortical pyramidal neuron AISs (5) is similar, approximately 40:1. Our studies suggest that relatively weak KCNQ2/3-AnkG binding contributes to this conductance density ratio. This ratio is physiologically and energetically advantageous, owing to the relatively hyperpolarized voltage-dependence and slow kinetics of KCNQ2/3 channel activation. These parameters allow KCNQ2/3 channels to strongly influence excitability in the subthreshold range, yet play a diminished role once threshold is passed (5,56,57).

Second, we mapped the AnkG sub-regions binding to the KCNQ2/3 and Na_v.1.2 anchor domains. We found that the strongest binding is contained within the first through seventh AnkG ankyrin repeats (R1-7), with weak but detectable additional binding elsewhere in MB. Work published by others while our paper was in preparation agrees with those findings (40,58). However, our mutagenesis of hairpin tips beyond R7 did not reveal any additional critical binding residues (data not shown). In particular, we were unable to find any evidence for KCNQ2/3 or Na_v.1.2 interaction with hairpins 13, 14, or 15 of AnkG implicated in binding the major cardiac sodium channel, Na_v.1.5 (41).

By deletion and substitution mutagenesis within R1-7, we identified different regions and key residues needed for Na_v and KCNQ2/3 binding. Alanine substitution of two arginine residues on the same face of the R1 front α-helix abolished KCNQ2/3 but not Na_v, channel binding (Fig. 7B-C; Fig. 10B-E, site 2). Replacing two lysines at the third hairpin tip abolished Na_v.1.2 binding, but only slightly diminished KCNQ2/3 (Fig. 10B-E, site 3). R7 deletion much reduced KCNQ3 binding, but had little effect on Na_v.1.2 (Fig. 9B-E, site 5). Of note, Wang et al. recently identified two phenylalanine residues on adjoining hairpin portions of repeats 4 and 5 (Fig. 10B-E, sites 4) that are critical for binding an unphosphorylated Na_v.1.2 peptide, and slightly reduced binding of an unphosphorylated KCNQ2 peptide (32). These in-solution biochemical studies are helpful guides for interpretation of already emerging and future structural studies (discussed below).

Third, we provide the first evidence for specific functional roles played by the alternatively spliced, non-ankyrin repeat, AnkG N-terminus. We found that 2 of 3 alternatively spliced AnkG N-termini strongly inhibit binding of KCNQ2/3 but not Na_v.1.2 anchors (Figs. 6E, 7B-C, 8, 9). This was unexpected, as these N-termini have to our knowledge not previously attracted any study, though they are very highly conserved and, like KCNQ2/3, are found only in vertebrates (Fig. 9A). Our findings can be summarized in a “gated binding pocket” model (Fig. 10). It is notable that an approximately 80 residue C-terminal domain in KCNQ2 and KCNQ3 is highly conserved across the vertebrates (3,24). The Na_v peptide domain which is highly conserved and functionally of primary importance for AnkG binding is much smaller, approximately 30 residues (22-24,34,43). Although structural information regarding the channel ligands is currently limited (discussed further below), an economical model is that the larger, phosphorylated KCNQ2/3 anchor domain may access the R1-7 binding region less easily than the analogous but smaller phosphorylated Na_v anchor.
Additional experiments will seek to further define mechanisms regulating the access of Na\(_v\) and KCNQ2/3 ligands to Ankyrin-G, and whether such access might be regulated dynamically in vivo. Although the Na\(_v\) and KCNQ2/3 anchor domains evolved in early vertebrate ancestors (basal chordates), the R1-7 repeats, including residues critical for binding, are much more ancient (39,59). Our findings both support and extend the “evolved fit” model of ankyrin interaction proposed by Bennett and colleagues a quarter century ago (11,12). In this model, roles of ankyrin in binding multiple ligands that are already established (in both evolutionary and developmental terms) underlie the high sequence conservation of the MB domain. Nonetheless, innovations arise when new ligands gain anchor motifs that evolve towards optimal affinity for binding to pre-existing AnkG surfaces. Here, the Na\(_v\) channel DII-III loop evolved the ability to occupy existing binding sites in the R1-6 region, probably in a basal, invertebrate chordate (24). The KCNQ2/3 ancestor gene evolved the ability to share this region 50-100 million years later, in a common ancestor of jawed vertebrate chordates. Many invertebrate ankyrin N-termini are short, 8-10 residues (Fig. 9A). The relatively lengthy (21-39 residue), highly conserved non-ankyrin repeat N-termini of vertebrates (Fig. 9A) evolved in the same interval as KCNQ channel AnkG binding. Growing the ankyrin gene in this way allowed for fine-tuning relative access of the two channels to their binding sites, while conserving the actual binding surfaces they share.

While our work was in final stages of preparation, Wang et al. reported two crystal structures including the R1 through R7 regions of Ankyrin B fused to two ligands; one of the ligands studied was a portion of the Na\(_v\)1.2 anchor peptide (32). This first glimpse at the main ankyrin KCNQ/Na\(_v\) binding region is very informative, most notably revealing how repeats 5 and 6 (encoded by a single, conserved exon) depart from the ankyrin canonical fold while adhering closely to its 33 residue, solenoidal periodicity. Our experiments implicate the same binding surface on AnkG shown to engage ligands by Wang et al. However, our CK2 phosphorylation results indicate that portions of Na\(_v\)1.2 and KCNQ2/3 up to 15-20 residues away from the Na\(_v\)1.2 peptide studied by Wang et al. are critical for ankyrin recognition. The completed work sets the stage for more refined mutational studies constrained by the known R1-7 structure. Future structural experiments should include the non-ankyrin repeat N-terminus, as well as larger and untethered portions of the channel anchor domains including CK2 phosphorylation sites. Phosphomimetic mutations at those sites may allow assessing the effect of CK2 phosphorylation on ankyrin-channel interactions.

Our studies highlight conserved vertebrate molecular mechanisms influencing neuronal excitability through control of the precise ratio of Na\(_v\) and KCNQ2/3 channels on axons. The findings shed light on causes of epilepsy and other neuropsychiatric disease arising from mutations in genes for AnkG and its channel ligands. Identification of the channel binding regions makes possible targeted screening for agents capable of modulating relative channel affinity and, thus, neuronal responsiveness. Treatments that inhibit Na\(_v\) binding or enhance KCNQ2/3 binding, thereby reducing the Na\(_v\)/KCNQ ratio at AISs and nodes of Ranvier, are candidate therapies for acute seizures, epilepsy and mood disorder.

Acknowledgments—We thank the members of the Cooper lab for helpful discussions, Angel Lopez for sharing unpublished results, and Baouyen Tran for critical reading of the manuscript. We thank the following investigators for generous gifts of cDNA clones: Vann Bennett (Duke Univ.) for AnkG-270 and neurofascin-186-HA, Thomas Jentsch (Leibniz-Institute for Molecular Pharmacology) for KCNQ2 and KCNQ3, and Robert J. Dunn (McGill Univ.) for Na\(_v\)1.2.

CONFLICT OF INTEREST: The authors declare that they have no conflicts of interest with the contents of this article.
AUTHOR CONTRIBUTIONS: MXX performed the experiments. MXX and ECC designed the study, analyzed the data and wrote the paper.

FIGURE LEGENDS

FIGURE 1. Cartoons showing the domain structures of Na,1.2, KCNQ2/3 and Ankyrin-G. A. Na,1.2 possesses 4 homologous domains (I-IV); the anchor motif recognizing AnkG (blue square) is located near the midpoint of the loop between domains II and III. The region fused to GST for pull down assays is indicated in red. B. KCNQ2/3 subunits possess 6 transmembrane segments, and an unusually long intracellular C-terminus. Two short α-helical segments representing sites for interaction with calmodulin (CaM, helices A, B) and two for subunit-subunit interaction (subunit interaction domain, SID, helices C, D) are labeled. Region used for GST fusions is shown in red: at the distal end is the AnkG binding motif (blue square). C. AnkG is large multi-modular protein containing a membrane binding (MB) domain; a spectrin binding domain (SBD), a C-terminal region including a very large exon domain (VLE), and a death domain.

FIGURE 2. GST-Na,1.2 DII-III loop, GST-Q2C and GST-Q3C binding to AnkG-MB is markedly enhanced by phosphorylation of the channel polypeptides by CK2. A. Alignment of AnkG binding regions of Na, and KCNQ2/3 channels. There are 4 predicted CK2 sites near the Na, anchor motif, 4 in KCNQ3, and 3 in KCNQ2. Blue arrowed arch: CK2 consensus sites; red asterisks: identical/same group amino acid between Na, and KCNQ2/3 channel. B. Pull down results. The indicated baits were first phosphorylated by CK2 (+ lanes). The baits were then mixed with lysates of HEK cells expressing AnkG-MB-GFP protein. Upper row: AnkG-MB-GFP in lysate (left lane), and the indicated pull downs, detected by western blot. Signal strength: Na,1.2>>KCNQ3>KCNQ2. After CK2 phosphorylation, pull down by all the three baits is greatly increased. At this exposure, CK (-) pulled down bands for KCNQ2 and KCNQ3 are barely detected. Lower row: Ponceau S staining of transfer membrane before western blot shows loading of GST fusion protein baits.

FIGURE 3. CK2 inhibition reduces the colocalization of overexpressed AnkG and KCNQ2 fusion proteins in HEK cells. A-F. Representative images and fluorescence correlation profiles for HEK293 cell co-expressing NF-Q2C with MB-GFP treated with DMSO (A, D, vehicle control), 50µM TBB (B, E), or 25µM TBCA (C, F); green versus red fluorescence correlation profiles are shown in rightmost column. In this profile, the X axis plots relative green fluorescence intensity (GFP, 0-100%); the Y axis give red fluorescence (Cy3 anti-HA, 0-100%). Region of interest (ROI) selected are indicated with yellow lines (Merged panels). G. Pearson correlation coefficient factors for conditions shown. The number of cells analyzed per condition, S.E.M, and t test results (***: p<0.001; **: p<0.01; *: P<0.05) are indicated. Scale bars: 10µm.

FIGURE 4. The N-terminal half of AnkG-MB (N-R12, ~400 residues) contains the KCNQ2 binding site responsible for surface redistribution. A. Cartoon showing MB domain exonic structure, encoded ankyrin repeats, and the overlapping truncations used to generate GFP fusion proteins. “+” indicates surface redistribution of GFP signal to the surface membrane was observed; “-” indicates GFP signal remained homogeneously cytoplasmic. B-E. Surface redistribution assay results. Left panels show cells labeled using an extracellular HA tag on the Neurofascin-KCNQ2 fusion protein bait; middle panels show the distribution of AnkG-GFP fusion proteins, right panels show overlays (AnkG-GFP, green; anti-HA, red). Below each panel, intensity histograms show signals along the yellow line. B-C. AnkG-MB (green) and N-R12 truncation (green) are redistributed to the cell surface. D-E. MB R11-17 (green) and MB R16-24 (green) remain cytoplasmic. Scale bars, 10µm.

FIGURE 5. AnkG-MB R1-7 is critical and sufficient for binding both Na,1.2 and KCNQ2/3 channel. A-D. GST pull downs of AnkG-MB truncations. A-B. Analysis of large fragments shows interaction of both channel with AnkG is primarily mediated by the N-terminal through R17 region, and is CK2 phosphorylation-dependent. Lanes 1-3: anti-GFP western blots of AnkG “prey” input. Lanes 4-9:
Pull down results. Upper row: CK2 phosphorylation-dependent binding to the GST-Na,1.2 DII-III loop (A) and GST-Q3C (B); lower row: Ponceau S staining shows equal loading of GST baits. C-D. Further specification of the binding region using deletional analysis. For each AnkG-MB prey, first row: prey input, second row: prey pulled down by the CK2 phosphorylated GST-Na,1.2 DII-III loop, third row: Ponceau S stain showing equal loading of baits (note, for N-R12 and N-R7 lanes, prey pulled down by Na,1.2 is detectable), fourth row: prey pulled down by the CK2 phosphorylated GST-Q3C, fifth row: Ponceau S stain for GST-Q3C E. Summary of mapping results from A-D. (R11-24 and N-R6, not shown). Pull down band intensity was rated as “+++”: very strongly positive; “++”: strongly positive; “+”: positive; “+/-”: weak but still detectable; “-/+”: barely detectable”.

FIGURE 6. Different residues within R1-7 are critical for Na, and KCNQ2/3 binding. A. Cartoon representing a single ankyrin repeat and the AnkG N-R7 fragment. Each 33 residue ankyrin repeat consists of a right-handed solenoid: half β-hairpin, two short antiparallel α-helices, a “loop” directed back towards the hairpin, and a second half β-hairpin. This pattern is followed in AnkG R1-7, except for R5-R6, which preserve the solenoidal periodicity but replace the hairpin with a longer R6 front helix, and longer loop (40). Locations of hairpin tips residues H1, H2, H4, H5, and H7 are labeled green; H3 tip KK implicated in Na, binding is labeled red. R47 and R50 residues implicated in KCNQ2/3 binding are labeled purple. B. Amino acid sequence of MB (N-R7) fragment, with ankyrin repeats aligned. R5-R6 secondary structure alignment is based on Wang et al., 2014 (40). C. AnkG-MB (N-R7) hairpin tip mutant pull-downs by CK2-phosphorylated GST-Na, DII-III loop. Upper and middle rows show prey input and prey pulled down, measured by anti-GFP western blot. The H3 KK to AA mutation shows strongly reduced binding, while the other hairpin tip mutants bind similarly to the control. Lower row: Ponceau S staining of the filter. Upper bands (*) are the GST fusion baits; lower bands (arrow) are the wild-type and mutated AnkG prey. D. Experiment performed in parallel with C, using CK2-phosphorylated GST-Q3C. MB (N-R7) H3 KK to AA mutation shows very slight reduction of binding to KCNQ3, while the other hairpin tip mutants show no obvious effects. E. Deletion of non-ankyrin repeat N-terminus from AnkG-MB (N-R24) leads to increased KCNQ channel binding activity. Deletion of R2-R3 repeats of full length MB leads to marked reduction of Na, channel binding activity. Na, and KCNQ3 baits were CK2-phosphorylated. F. Summary of the results in E; scale as in Fig. 5E

FIGURE 7. Two arginines on the repeat 1 front α-helix are critical for KCNQ2/3 but not Na,1.2 channel binding. A. The AnkG N-terminus and first repeat, with residues mutated highlighted: positive charged residues (green shading), cluster including multiple acidic residues (red shading), single acidic residue (pink box). B-C. GST pull downs of AnkG-MB (N-R7) and (R1-7) with and without R47A, R50A mutations, and (D-F) of AnkG-MB (N-R7) with and without the indicated mutations in the N-terminus. B. Anti-GFP westerns are shown: upper: prey input, middle: prey pulled down by CK2-phosphorylated GST-Na, DII-III loop, lower: prey pulled down by CK2-phosphorylated GST-Q3C. The R47A, R50A mutation abolishes KCNQ3 binding, but Na, channel binding is unaffected. C. GST-Q2C pull down AnkG-MB (N-R7); AnkG-MB (N-R7) R47R50 mutation; (R1-7); AnkG-MB (R1-7) R47R50 mutations with or without CK2 activity. Upper: prey input, middle: prey pulled down by GST-Q2C, lower: prey pulled down by CK2-phosphorylated GST-Q2C. CK2 phosphorylation and N-terminal deletion additively increase binding. Lanes c’-d’ are briefer exposures. D-F. Mutations within the NT3 N-terminal have no affects. D. Western blots showing pull downs by GST-Na, DII-III and GST-Q3C. E-F. Pull downs of additional mutant constructs, showing both western blots and Ponceau stains. In GST-Na, 1.2 DII-III but not GST-Q3C pulldowns, Ponceau staining reveals both the bait (*) and the AnkG prey. For both baits, the mutations have no effect on pull down results.

FIGURE 8. R47A, R50A mutation within the first ankyrin repeat reduces AnkG colocalization with NF-Q2C. A-G. Images and fluorescence correlation profiles for representative HEK293 cells co-expressing NF-Q2C with GFP fusion constructs. For each condition, images show (left to right) DAPI labeling of the nucleus, GFP fluorescence, immunofluorescent staining for the HA-NF-Q2C fusion
A. GFP alone gives a diffuse pattern, unlike the punctate intracellular and surface “edge” pattern of NF-Q2C. This results in an intensity correlation profile (right) showing poor correlation. B. MB-GFP shows a punctate and surface pattern similar to NFQ2C, and high correlation. MB Ndel-GFP (C), MB R47,50-GFP (D), MB Ndel R47,50-GFP (E), MB R1-7-GFP (F), or MB R1-7 R47,50-GFP (G). H. Quantification of co-localization of NF-Q2C with GFP fused AnkG MB fragment mutants for cells in A–G. Pearson correlation coefficient factors for conditions shown. The number of cells analyzed per condition, S.E.M, and t test results (***: p<0.001; **: p<0.01) are indicated. Scale bars: 10µm.

FIGURE 9. AnkG N-termini NT1, NT2 and NT3 inhibit KCNQ2/3 but not Na,1.2 binding to AnkG. A. Amino acid sequences of alternative N-termini of human AnkG, N-terminus of zebrafish Ank3a (ZDB-GENE-060621-1) and fly ankyrin-2 (GenBank: NP_001097533), aligned at point of attachment to MB. The NT3 terminus is very highly conserved between fish and man; the invertebrate N-terminus shows no apparent homology. B. Splicing diagram at the 5’ region of ANK3; this pattern is conserved in vertebrates, absent in invertebrates. C. Western blots of pull down experiments using AnkG R1-7 bearing different N-termini (lanes 1-3) or without an N-terminus (lane 4). Upper row: lysate inputs, detected using anti-GFP; middle row: prey pull downed by CK2-phosphorylated GST-Na,1.2 DII-III loop; lower row: prey pull downed by CK2-phosphorylated GST-Q3C. NT2 and NT3 strongly inhibit, and NT1 less strongly inhibits binding to GST-Q3C, but not to GST-Na,1.2 DII-III

FIGURE 10. “Gated binding pocket” model for differential Na, and KCNQ2/3 channel binding to Ankynin-G. A. Chou Fasman secondary structure algorithm predicts the NT3 N-terminus forms an α-helix (grey) followed by a 3-4 residue turn (red), linked to downstream ankyrin repeats. B-E. Model summarizing results of the current study, also considering results of Wang et al. (40). Five determinants of binding are shown: (1) the N-terminus, (2) repeat 1 helix RR, (3) hairpin 3 KK, (4) two F residues on hairpins 4 and 5 (40), (5) repeat 7. The non-ankyrin N-terminal (grey) together with ankyrin repeats R1-7, (helices: green circles; top: green line; loop and hairpin, brown) surround a binding pocket (blue oval). In the preferred “tight” conformation of the pocket (B-D), the smaller Na, anchor domain accesses its binding sites more easily than the larger KCNQ2/3 anchor domain.
