Edited by Ronald C. Wek

N-Formylation of the Met-tRNAverb Met by the nuclearly encoded mitochondrial methionyl-tRNA formyltransferase (MTFMT) has been found to be a key determinant of protein synthesis initiation in mitochondria. In humans, mutations in the MTFMT gene result in Leigh syndrome, a progressive and severe neurometabolic disorder. However, the absolute requirement of formylation of Met-tRNAverb Met for protein synthesis in mammalian mitochondria is still debated. Here, we generated a Mtfmt-KO mouse fibroblast cell line and demonstrated that N-formylation of the first methionine via fMet-tRNAverb Met by MTFMT is not an absolute requirement for initiation of protein synthesis. However, it differentially affected the efficiency of synthesis of mtDNA-coded polypeptides. Lack of methionine N-formylation did not compromise the stability of these individual subunits but had a marked effect on the assembly and stability of the OXPHOS complexes I and IV and on their supercomplexes. In summary, N-formylation is not essential for mitochondrial protein synthesis but is critical for efficient synthesis of several mitochondrial encoded peptides and for OXPHOS complex stability and assembly into supercomplexes.

In mitochondria, synthesis of proteins requires tightly coordinated communication between nuclear and mitochondrial DNA. Although the majority of proteins required for the process are encoded in the nuclear DNA, translated in the cytoplasm, and imported to mitochondria (1), 13 proteins that are catalytic subunits of the oxidative phosphorylation (OXPHOS)4 system are synthesized inside mitochondria.

These proteins are encoded by the mammalian mitochondrial DNA (mtDNA) along with 22 tRNAs and two ribosomal rRNAs required for their synthesis. The current model of mitochondrial protein synthesis is divided into three conserved steps as it occurs in cytoplasm: initiation, elongation, and termination. In mammalian mitochondria, the initiation step acts as a major checkpoint and rate-limiting factor in protein synthesis (2). The nuclearly encoded protein methionyl-tRNA formyltransferase (MTFMT) is responsible for adding a formyl group to a portion of the single mitochondrial Met-tRNAverb Met (3). Once the Met-tRNA is acylated/aminoacylated with methionine (Met-tRNAverb Met) and N-formylated by MTFMT (fMet-tRNAverb Met), it is recognized by the initiation factor mtIF2 (a translational GTPase) before it binds to the small mitoribosomal subunit (SSU)–mRNA complex (2, 3). Following this, hydrolysis of GTP into GDP facilitates the binding of the large mitoribosomal subunit (LSU) and completes the formation of the initiation complex allowing elongation to start (4).

Although N-formylation is considered a requirement for initiation of protein synthesis in mitochondria and most bacteria, it cannot be easily generalized across species or domains of life. For example, in different bacterial species, the absence of N-formylation has been shown to strongly impair cellular growth (Escherichia coli) (5), reduce viability (Streptococcus pneumoniae, Mycobacterium smegmatis, and Mycobacterium bovis) (6), or have only minor effects in others (Pseudomonas aeruginosa) (7). In lower eukaryotes such as Saccharomyces cerevisiae, N-formylation is not essential (8). In humans, different compound heterozygous mutations in MTFMT were identified in a subset of patients diagnosed with Leigh syndrome, a severe neurometabolic disorder combined with OXPHOS dysfunction (9–15), demonstrating that N-formylation is critical for OXPHOS function. Furthermore, studies in fibroblasts of patients harboring mutations in the MTFMT gene showed reduced activity of complex I and/or IV and in some cases complex V, supporting the critical role of N-formylation for mitochondrial OXPHOS function.
The role of mitochondrial methionyl N-formylation

MTFMT expression is required for the N-formylation of mitochondrial Met-tRNA^{Met} in patients, but there is still controversy about the absolute requirements of N-formylation for mitochondrial protein synthesis. Four compound heterozygous patients studied sharing the common c.626C→T mutation allele in the MTFMT gene showed absence of MTFMT protein expression levels (9, 13, 14) and no detectable levels of mitochondrial fMet-tRNA^{Met} (9, 13). However, all mutant fibroblasts still had mitochondrial protein synthesis, albeit at decreased efficiency.

Contradictory results were also described for the N-formylation of COI, a mitochondrially encoded subunit of complex IV. In one study, using mutant MTFMT fibroblasts, most of the COI was not assembled into complex IV and was not N-formylated, suggesting that N-formylation of COI is required for assembly into complex IV (13). However, this finding contrasts with a previous study where, in the absence of detectable levels of MTFMT expression, N-formylation of COI was still observed (9).

The c.626C→T mutation is not only predicted to eliminate two exon splicing enhancers, resulting in a nonfunctional protein (9), but also a missense mutation and a S209L substitution. The authors suggested that residual activity of the S209L mutant MTFMT protein (16) could explain the observed mitochondrial protein synthesis and the detection of N-formylated COI found in one study (9).

To clarify the function of MTFMT in mammals, we generated a complete Mftmt knockout (KO) in mouse fibroblasts to determine whether N-formylation on Met-tRNA^{Met} by MTFMT is an absolute requirement for protein synthesis initiation in mammalian mitochondria. We also evaluated the effects of complete ablation of Mftmt on the synthesis and stability of the 13 mitochondrially encoded proteins, individual OXPHOS complexes, and their association into supercomplexes.

Results

Mtfmt homozygous knockout fibroblasts do not express MTFMT protein

To generate a complete Mtfmt-KO model ex vivo, we deleted the exon 4 of the Mtfmt gene in mouse skin fibroblasts using the cre-loxP technology (17). Exon 4 flanked by loxP sites was deleted using a plasmid expressing cre recombinase under the control of the CMV promoter. Deletion of exon 4 is predicted to result in the synthesis of a truncated protein. Exon 4 is present in all transcript isoforms and is where the most frequent disease mutation (c.626C→T) has been found in patients with mutations in the MTFMT gene. After clonal selection and expansion, we confirmed the successful deletion of exon 4 by amplification of the deleted fragment by short PCR in the Mtfmt-KO fibroblast clones and the absence of this fragment in the parental loxP/loxP clone (Fig. 1A). We did not detect MTFMT by Western blotting using enriched mitochondrial crude extracts in different Mtfmt-KO fibroblast clones (n = 3) (Fig. 1B). These observations confirmed the generation of a complete Mtfmt knockout model in mouse fibroblasts. KO cells grew normally in enriched high-glucose medium, and gross mitochondrial distribution (by MitoTracker staining) also appeared similar to controls (not shown).

Mitochondrial MTFMT is responsible for N-formylation of the Met-tRNA^{Met} in mammalian mitochondria

In mammalian mitochondria, once the unique tRNA^{Met} is acylated/aminoacylated by the methionyl-tRNA synthetase, the MTFMT adds a formyl group to a portion of Met-tRNA^{Met}. To evaluate the activity of the MTFMT, we measured the steady-state levels of the three forms of the mitochondrial tRNA^{Met}; deacetylated (tRNA^{Met}), aminoacylated (Met-tRNA^{Met*}), and aminoacylated and N-formylated (fMet-tRNA^{Met*}). These were identified by high-resolution Northern blot analysis using the cytoplasmic (Met-tRNA^{Met*}) as a negative control of N-formylation. After isolation of total RNA under acidic conditions to maintain both Met-tRNA^{Met} and fMet-tRNA^{Met*}, we detected the three forms of tRNA^{Met} in the Mtfmt control clones (Fig. 2A), which showed lower amounts of
The role of mitochondrial methionyl N-formylation

Absence of MTFMT activity may affect the regulation of the tRNA\textsubscript{Met} ratios in mammalian mitochondria.

N-Formylation is not an absolute requirement for mitochondrial protein synthesis in mammalian mitochondria

To evaluate the effects of MTFMT absence on mitochondrial protein synthesis, we measured the metabolic incorporation of radiolabeled [\textsuperscript{35}S]Met-Cys in the 13 mitochondrially encoded proteins in the presence of an irreversible inhibitor of cytoplasmic ribosomes (emetine). Using a short pulse (15–30 min), we observed the synthesis of all 13 mitochondrially encoded proteins in the Mtfmt-KO cell clones relative to Mtfmt controls (Fig. 3A). Interestingly, the rate of synthesis varied among the individual subunits (Fig. 3C). It was drastically reduced for ND4 (83%) followed by subunits ND4L (59%), COI (57%), ND6 (56%), ND1 (53%), and COIII (47%). It was not significantly altered for subunits CYTB (35%), COII/ATP6 (33%), ND3 (20%), and ATP8 (130%). ND5 and ND2 subunits from complex I were not detected, suggesting that both proteins have a low rate of synthesis in this fibroblast cell model as they could be observed in pulse-chase experiments (Fig. S2). The ND1 subunit not only showed a decreased rate of synthesis in the Mtfmt-KO clones but also faster migration relative to control cells (Fig. 3B, enlarged panel). We did not detect this migration difference in two different mouse cell models of complex I deficiency (Ndufs3-KO) and complex IV deficiency (Cox10-KO) (Fig. S1), which indicates that the absence of N-formylation not only affects the rate of synthesis but has an additional effect on the electrophoretic mobility of this subunit. The lack of specific antibodies made it difficult to address this question as we could not isolate ND1 to sequence the N terminus.

Altogether, these results demonstrated that, in mammals, mitochondrial protein synthesis occurs in the absence of N-formylation. However, lack of N-formylation compromised the efficiency of synthesis of the 13 mitochondrially encoded polypeptides to different degrees.

Absence of N-formylation does not have a marked effect in the stability of mitochondrially encoded polypeptides

We then wanted to investigate whether the absence of N-formylation has any effect on the stability of the newly synthesized mitochondrially encoded polypeptides. For that, we determined the rate of degradation of each polypeptide in the Mtfmt-KO cell clones relative to controls using the pulse-chase radiolabeling assay and measuring the rate of [\textsuperscript{35}S]Met-Cys incorporation at two different chase times (9 and 18 h). In this assay, cells were pretreated with chloramphenicol (a reversible mitochondrial protein synthesis inhibitor) for 24 h, which results in the accumulation of the nuclearly encoded components required for mitochondrial protein synthesis.

Pulse labeling with [\textsuperscript{35}S]Met-Cys detected all mitochondrially encoded polypeptides, including subunits ND5 and ND2 in the Mtfmt-KO cells, confirming the synthesis of both subunits in the absence of N-formylation (Fig. S2). After a 9-h chase, the rate of degradation as well as the turnover in Mtfmt control cells varied among the individual subunits. ND5 subunit was no longer detected at 9 h, most likely due to the fast turnover rate compared with the other subunits. This was followed by sub-

The deacylated tRNA\textsubscript{Met} form and almost equal amounts of fMet-tRNA\textsubscript{Met} and Met-tRNA\textsubscript{Met} (Fig. 2B). In contrast, in the Mtfmt-KO fibroblast clones, we did not detect fMet-tRNA\textsubscript{Met} and interestingly, the KO clones showed preferential accumulation of the aminoacylated Met-tRNA\textsubscript{Met} with two of three mutant clones showing lower levels of deacylated tRNA\textsubscript{Met} (Fig. 2, A and B). We observed a marked increase of total mitochondrial tRNA\textsubscript{Met} levels (Fig. 2C), similar to previous results in humans (9). These results indicate that MTFMT is required for N-formylation of the Met-tRNA\textsubscript{Met} and suggest that the
units ND2, ND3, and ND4L, which were detected at lower intensity, suggesting that the turnover of this group of proteins is quicker compared with the other remaining subunits (Fig. S2). The rate of degradation in Mtfmt-KO cells relative to controls was determined as the percent decrease of [35S]Met-Cys–incorporated label from the pulse time point (0.5 h) (Fig. 4). We found that, although the stability of the ATP8 subunit decreased in the Mtfmt-KO cells at 9-h chase (p < 0.01) and the stability of the ND4 subunit had a trend to decrease in Mtfmt-KO cells, the remaining subunits had very similar rates of degradation. We validated these results by measuring and comparing the rate of degradation in our model with the rate of degradation in bona fide complex I- and IV-deficient cell models (Fig. S3). We found that the stability of certain subunits was highly compromised and varied depending on the model studied (Figs. S4 and S5), which confirms that the absence of N-formylation does not have a major effect on the stability of the mitochondrially encoded proteins.

Absence of N-formylation affects the steady-state levels of OXPHOS complexes

We tested whether the lack of MTFMT, either by reduced efficiency of synthesis of the mitochondrially encoded subunits or by any other mechanism, has an effect on the steady-state level of OXPHOS components. We measured the steady-state levels of different mitochondrial markers by immunoblotting (Fig. 5) and found that NDUF88, a late-stage subunit during the assembly of complex I, decreased in the Mtfmt-KO cells (p < 0.007), whereas NDUFA9, an early-stage assembly subunit of the hydrophilic arm of complex I, did not.

Steady-state levels of COIV, a nuclearly encoded subunit essential for assembly of complex IV, was markedly decreased (p < 0.006) in the Mtfmt-KO cells. We did not detect significant changes in the steady-state levels of COI; succinate dehydrogenase complex flavoprotein subunit A (SDHA), a catalytic subunit of complex II; ubiquinol-cytochrome c reductase core pro-
tein I (UQCRC1), a core subunit component of complex III; and ATP synthase subunit α (ATP5A), a subunit of complex V.

Absence of N-formylation affects preferentially complexes I and IV and assembly into supercomplexes

We then analyzed the assembly of the individual OXPHOS complexes and their interactions into supercomplexes. We detected these macrocomplexes using blue native polyacrylamide gel electrophoresis (BN-PAGE) after solubilization with digitonin. In Mtfmt control cells, the majority of detected complex I was preferentially assembled into the respirasome structure corresponding to the CI–CIII2–CIVn form and the supercomplex CI–CIII2 with a small portion still detected in the isolated CI form. In contrast, in the Mtfmt-KO clone cells, there was a significant decrease of total complex I (70%) with the presence of CI–CIII2 but no detectable levels of CI–CIII2–CIVn or free CI (Fig. 6, A and B), indicating that the absence of N-formylation had profound consequences to complex I levels and its association into supercomplexes.

In the case of complex III, Mtfmt control cells showed preferential association into supercomplexes CI–CIII2–CIVn and CI–CIII2 with low levels of free complex III. In the Mtfmt-KO cells, complex III instead was lost from the CI–CIII2–CIVn but was highly increased in the free and CI–CIII2 forms. The levels of complex IV decreased by 60% in the Mtfmt-KO cells, whereas total complex II levels showed a significant increase, possibly as a compensatory mechanism. Analysis of complex V did not show any change in the Mtfmt-KO cells; however, there was a slight increase in the nonmembrane-embedded module termed F1. Altogether, these results indicate that the absence of N-formylation affects preferentially the assembly of individual complexes I and IV and the supercomplex interactions, mostly in the CI–CIII2–CIVn form. We also evaluated the activity of the individual complexes I and IV and supercomplexes using BN-PAGE in-gel activity and found a pattern of activity nearly identical, indicating that disruption of OXPHOS complex assembly correlates with the observed decrease in activity of individual complexes I and IV at complex and supercomplex levels (Fig. 6C).

Absence of N-formylation results in increased glycolysis rate in Mtfmt-KO cells

To identify the physiologic effects of MTFMT absence in mitochondrial and cellular bioenergetics, we measured the oxygen consumption rate (OCR) and extracellular acidification rate (ECAR) in Mtfmt-KO intact cells and compared them with controls using the XFp extracellular flux analyzer (Seahorse Biosciences).
Basal respiration was decreased by 22% in the Mtfmt-KO cells (Fig. 7A). ATP-linked respiration did not change nor did maximal respiratory capacity (Fig. S6A). Consequently, spare respiratory capacity (OCR difference between the basal and maximal respiratory capacities) increased by 59%. Although we cannot explain the unaltered maximum respiration, the increase in spare respiratory capacity could be a consequence of alternative substrate utilization under uncoupled conditions in the KO cells.

Conversely, basal glycolysis in the Mtfmt-KO cells increased by 40% (p = 0.0055) (Figs. 7B and S6). Subsequent addition of oligomycin to inhibit ATP from oxidative phosphorylation did not change the glycolytic capacity of KO cells relative to control. There was a 38% decrease in glycolytic reserve (Fig. 7B), reflecting the adaptation of Mtfmt-KO cells to glycolysis.

**Discussion**

N-Formylation of Met-tRNA\textsuperscript{Met} by the MTFMT enzyme is an exclusive mechanism of mitochondrial protein synthesis in eukaryotes. However, in mammals, the absolute requirement of N-formylation to start mitochondrial protein synthesis is still debated. In this study, we generated a Mtfmt-KO mouse fibroblast cell clone model, deleting exon 4 of the Mtfmt gene, which in humans harbors the most frequent pathogenic allele, c.626C→T. We confirmed the complete deletion of exon 4 at the DNA level and did not detect the MTFMT protein, demonstrating the generation of Mtfmt-KO mouse cell lines. Because this region is required for activity (16, 18), its ablation leads to the formation of a null allele as confirmed by our findings. The availability of a complete KO allowed us to study the role of MTFMT in a well defined genetic background.

Initially, we observed that N-formylation of the mitochondrial Met-tRNA\textsuperscript{Met} was lacking in the Mtfmt-KO fibroblast clones, confirming that MTFMT is required for N-formylation of the Met-tRNA\textsuperscript{Met} in mouse mitochondria. Our analysis of the tRNA ratios indicated that, in mouse fibroblast control cells, the three forms of mitochondrial tRNA\textsuperscript{Met} are maintained at approximately equal ratios. Studies with human fibroblasts showed preferential accumulation of the N-formylated and deacylated forms (9). However, the significance of this variation is unknown. It is generally accepted that only a portion of the unique Met-tRNA\textsuperscript{Met} inside mitochondria is N-formylated as fMet-tRNA is needed only for initiation. However, it is not known how these ratios are regulated and how they affect mitochondrial protein synthesis. Tucker et al. (9) reasoned that, in human fibroblasts, the low levels of Met-tRNA\textsuperscript{Met} could be a result of its rapid use during the elongation process. In contrast, in mouse, the aminoacylated tRNA\textsuperscript{Met} proportion was not significantly changed in the KO cells. However, it is not known how these ratios are regulated and how they affect mitochondrial protein synthesis. Tucker et al. (9) reasoned that, in human fibroblasts, the low levels of Met-tRNA\textsuperscript{Met} could be a result of its rapid use during the elongation process. In contrast, in mouse, the aminoacylated tRNA\textsuperscript{Met} proportion was not significantly changed in the KO cells.

Our findings show that MTFMT is essential for the mitochondrial translation of proteins, as a result of its exclusive role in the initiation of mitochondrial protein synthesis. In conclusion, N-formylation of Met-tRNA\textsuperscript{Met} is required for mitochondrial protein synthesis.

**Figure 5. Absence of N-formylation affects the steady-state levels of OXPHOS complexes.** A, representative Western blots from total protein lysates show decreased levels of NDUFB8 subunit (***, p < 0.007) of complex I (C-I) and COIV (**, p < 0.006) of complex IV (C-IV) in Mtfmt-KO cells. No significant changes were observed in other OXPHOS markers. B, values are expressed as a percentage of CTR and represent the mean (error bars represent ± S.D.) of three independent experiments (three clones each) for NDUFB8, NDUFA9, and COI or three clones for the other markers. Vinculin (VINC.) and tubulin (TUB.) were used as loading controls. Vinculin blots were the same for CIV and SDHA, NDUFA9 and NDUFB8; TIM23 and ATP5A, and UQCRC1. Tubulin was the loading control for COI. Two-tailed t test was used for statistical analyses.
Figure 6. Absence of N-formylation affects assembly of complexes I and IV and supercomplexes. A, analysis of OXPHOS complex and supercomplex assembly was done by BN-PAGE in the presence of digitonin followed by Western analyses using the antibodies in parentheses to identify each complex. Note the nearly absent CI–CIII2–CIVn supercomplex and decreases in complexes I and IV. All values were normalized to TIM23; F1, ATP synthase F1 complex. B, data are presented as the mean (error bars represent ± S.D.) of three clones, and unpaired two-way ANOVA was used for statistics (*, p < 0.05; **, p < 0.01; ***p < 0.001). Total levels of complexes I, II, III, IV, and V were analyzed using unpaired two-tailed Student’s t test. C, BN-PAGE in-gel activity showed decreased activity of free CI and supercomplexes (CI–CIII2 and CI–CIII2–CIVn) in Mtfmt-KO cells and decreased free CIV activity. TIM23 was used as a loading control. CTRL, control.
The role of mitochondrial methionyl N-formylation

Met-tRNAMet, which indicates that N-formylation of the Met-tRNAMet is not an absolute requirement of mitochondrial protein synthesis in mammals, but instead N-formylation has a critical role in the efficiency of synthesis and possibly assembly of certain mitochondrially encoded proteins.

It is widely accepted that mitochondria are derived from bacteria, and, therefore not surprisingly, the mitochondrial translational machinery shares many features, including the N-formylation of the Met-tRNAMet to be used in initiation. One interesting evolutionary question is whether mitochondria continue to rely on N-formylation for protein synthesis or whether they can function without it. N-Formylation of Met-tRNAMet was already shown to be dispensable in certain bacteria, such as *P. aeruginosa* (7), and yeast (2), providing the first clue that, at least in lower eukaryotes, formylation of the mitochondrial initiator tRNA is not an absolute requirement. In mammals, bovine mitochondrial mtIF2 initiation factor strongly prefers N-formylated fMet-tRNAMet over nonformylated Met-tRNAMet (19, 20). Conversely, bovine mtIF2 also supports protein synthesis in yeast mutants without formylated initiator tRNA (21). Our data provide evidence that the mammalian mitochondrial translational machinery can function without MTFMT but not as efficiently.

Interestingly, in our mouse model, we found that the effect on the efficiency of synthesis is different for the various mitochondrially encoded polypeptides. In this model, the absence of *N*-formylation affected drastically the rate of synthesis of the ND4 subunit, but less of an effect for others (ND1, ND4L, ND6, COI, COII/ATP6, and COIII), and had no significant effects in the rates of CYTB, ATP8, and ND3 subunits. In humans, two other studies (13, 14) have reported a preferential rate of decrease for the subunits ND1, ND5, ND4, and COII. However, it is not known whether this differential susceptibility is species-specific, whether it correlates with the structural properties of each subunit during assembly, or whether it is connected to additional functional roles of N-terminal formylation of mitochondrially encoded proteins, such as the generation of N-formyl peptides. In humans, N-formylated hexapeptides such as ND4, ND6, and COI are agonists of formyl peptide receptor-1 and induce chemotactic cellular responses involved in the modulation of the immune response (22, 23).

We also observed a differential migration in the ND1 subunit in SDS gels. We excluded the effect of polymorphisms in this *Mtfmt*-KO mouse model, which have been considered to be a major source of differences in the electrophoretic migrations observed in pulse experiments (24, 25). Interestingly, by reviewing SDS gels in the literature, this differential migration pattern can also be observed in one of the patients (P1) with mutations in *MTFMT* (13). Despite our attempts, efforts in sequencing the N-terminal region of ND1 were unsuccessful, mostly because there are no effective antibodies against the mouse ND1 that allowed for immunoprecipitation and MS sequencing of the N terminus. We speculate that this change in molecular weight could reflect an alternative mechanism of synthesis in response to the absence of N-formylation, such as the use of an alternative start codon for initiation or other mechanism yet to be discovered. In fact, ND1 in mouse is the only subunit that uses GUG (coding for valine) as initiator instead of a canonical codon (AUN).

The absence of N-formylation did not cause a major effect on the stability of the mitochondrial subunits in the mouse *Mtfmt*-KO cells as demonstrated by the pulse-chase experiments at 9 and 18 h. However, we showed that the absence of N-formylation did affect preferentially the steady-state levels of individual complexes I and IV and drastically impacted the organization into the CI–CIII2–CIV supercomplex. Although this could be a simple consequence of decreased steady-state levels of mtDNA-coded subunits, it may also point to a role for N-formylation in complex assembly. The physiological role of supercomplexes is still debated, but destabilization of these supramolecular assemblies could reduce efficiency of ATP production in homeostasis or stress situations (26). The assembly of complex I was the most severely affected with ~70% total reduction in BN-PAGE and loss of the major supercomplex organization. Complex I has seven subunits translated in the mitochondria that are critical components of the proton translocation membrane arm. In the absence of N-formylation, at least two subunits, ND4 and ND1, showed lower levels or differential migration, respectively. There was also a decrease in
steady-state levels of the nuclearily encoded transmembrane helix NDUF8, which was shown to interact with ND4 subunit during complex I assembly, suggesting that the N-formyl residue may have a role in the assembly process of these subunits into individual complexes, which consequently may affect their interaction and stability in supercomplexes.

Absence of N-formylation did not affect the total levels of complex III in the Mtfmt-KO cells, which correlated with the normal steady-state levels of the mitochondrial UQCRC1, a core subunit of complex III, and no changes in efficiency of synthesis of the only mitochondrially encoded complex III subunit, CYTB. However, there was a marked effect in the supramolecular organization of this complex. In the absence of N-formylation, complex III accumulated preferentially in the free form with reduction of CI–CIII2 association and loss of the major CI–CIII2–CIV supercomplex. Complex III has been shown to be required for stability of complex I (27) and to be preferentially organized into the CI–CIII2 supercomplex under normal physiological conditions (28), which suggest that these changes in supercomplex organization could result primarily from the drastic decrease of complex I.

Complex IV, in contrast, showed 60% decreased levels in the absence of N-formylation, which correlated with the significant decrease in efficiency of de novo protein synthesis of mitochondrially encoded subunits COI and COIII and the drastic decrease in steady-state levels of the nuclearly encoded COIV, an assembly factor of complex IV, indicating an important role of N-formylation not only in the assembly/stability of this individual complex but also in the drastic effects on the major CI–CIII2–CIV supercomplex association.

It is still unclear whether N-formylation contributes to the structural stability of the supramolecular structure. Electrospray ionization MS in bovine heart mitochondria identified that, with the exception of the COIII subunit, all 12 mitochondrially encoded proteins retain the N-formyl group (29). Studies of complex IV assembly in patient fibroblasts with mutations in MTFMT have shown a severe decrease in N-formylated COI in the assembled complex IV, indicating that the N-formyl residue of the COI may facilitate assembly into the complex (13). However, in a previous study, N-formylated COI was detected as the most abundant form in two patient fibroblasts with mutations in MTFMT (9). Although it is not known what caused these contrasting differences, further studies in the mouse model should help elucidate the effects of the absence of N-formylation in complex IV assembly and correlate them with the human counterpart.

Assembly/stability of individual complex V was not affected in absence of N-formylation, which correlated with no changes in the steady-state levels of the mitochondrial membrane ATP5A. The increased levels of ATP8 from complex V also showed normal rate levels, which indicates that the absence of N-formylation does not have a major effect on the mitochondrially encoded subunit part of these complexes.

The functional implications of the absence of N-formylation in the Mtfmt-KO mouse model were reflected by the reduction of activity of individual complex I and complex IV and the levels of the major CI–CIII2–CIV supercomplex. These likely explain the decrease of the basal mitochondrial respiration rate and the switch to glycolysis to maintain the overall energy demand. This suggests a metabolic adaptation of the Mtfmt-KO cells and a compromised ability to respond to stress. This is also in agreement with the lactic acidosis observed in patients with Leigh syndrome and MTFMT mutations and could provide insights into the clinical variability and onset of the disease (10, 12).

In summary, we have generated Mtfmt-KO fibroblast mouse cell lines and confirmed that N-formylation is not an absolute requirement for mitochondrial protein synthesis in mice; however, it is critical for efficiency of synthesis of certain mitochondrially encoded subunits. Absence of N-formylation does not affect stability of the de novo synthesized subunits but instead affects drastically the assembly/stability of complexes I and IV, which has profound effects on their association into supercomplexes. The absence of N-formylation results in increased reliance on glycolysis for energy production. Although cultured fibroblasts showed normal growth and survival without MTFMT, it is possible that N-formylation is critical for optimal OXPHOS function in specific tissues or stress situations. Future experiments with animal models will help answer these questions.

**Experimental procedures**

**Generation of the ex vivo Mtfmt knockout cell model**

Dermal fibroblasts were derived from skin tissue explants from 3-month adult homozygous MtfmtloxP/loxP mice followed by immortalization and transfection with the CMV cre recombinase (cre) plasmid as described elsewhere (17). Confirmation of successful recombination using cre transgene expression ex vivo was done by amplifying the putative deleted region in the Mtfmt gene after cre recombinase activity by short PCR using specific primers. DNA was extracted from the parental MtfmtloxP/loxP clone and Mtfmt-KO clone cells.

**Cell culture conditions**

Mouse fibroblast MtfmtloxP/loxP controls and Mtfmt-KO cells were grown in T 75-cm² cell culture flasks using high-glucose DMEM supplemented with fetal bovine serum (15%; Sigma), sodium pyruvate (1 mM), nonessential amino acids (1 ×), uridine (0.1 mg/ml), and gentamicin (20 mg/ml; all obtained from Gibco). Cells were maintained at 37 °C and 5% CO2. Mtfmt control cells were used between passages 30 and 50, and Mtfmt-KO cells were used between passages 20 and 30. Other controls used in these experiments, such as the mouse fibroblast cell line NIH3T3, were grown in the same cell culture conditions. All the cells used in the study were tested for Mycoplasma contamination by PCR. Control (CTR) clones 1–3 were selected after immortalization. KO clones 1–3 were derived from the same parental clone, identified as CTR 2. The same controls and knockouts are shown consistently throughout the study.

**Mitochondrial extraction**

Mitochondrially enriched fractions were obtained by a nitrogen cavitation method with slight modifications from Gottlieb and Adachi (30). In brief, cells were grown to 90% confluence and collected using 0.05% trypsin, EDTA (Gibco). The pellet...
was washed in cavitation buffer A (100 mM sucrose, 1 mM EGTA, 20 mM MOPS, pH 7.4, 1 g/liter BSA (Sigma). The new pellet obtained was resuspended in cavitation buffer B (cavitation buffer A plus 10 mM triethanolamine and 5% (w/v) Percoll (Sigma) supplemented with protein inhibitor mixture (Roche Applied Science)) and placed in the cavitation vessel. Cell disruption was achieved using nitrogen gas to 600 p.s.i. and allowed to equilibrate for 30 min. Cells were collected by differential centrifugation (2500 and 15,000 rpm) to separate the crude mitochondrial pellet and stored at −80 °C.

**Mitochondrial translation assays**

Cells were grown to 90% confluence in 6-well plates. Mitochondrial protein synthesis was performed in L-methionine-L-cysteine–free DMEM (1×) supplemented with fetal bovine serum (10%) and sodium pyruvate (1 mM) from Gibco. Cells were incubated for 10 min with emetine (100 μg/ml) as an irreversible cytoplasmic protein inhibitor during the pulse experiments and with anisomycin (100 μg/ml) as a reversible cytoplasmic protein inhibitor during chase experiments. For the chase experiments only, cells were pretreated with chloramphenicol (40 μg/ml) for 24 h. All reagents were obtained from Sigma.

Approximately 400 μCi/ml EXPRESS35S methionine-cysteine protein labeling mixture (PerkinElmer Life Sciences) was added to the medium, and the radioisotope labeling was performed for at least 15–30 min. This followed a short incubation of 5 min with DMEM supplemented with fetal bovine serum (10%) and sodium pyruvate (1 mM) prior to cell collection. For the chase experiments, cells were metabolically labeled for 30 min (pulse) and chased at two time points (9 and 18 h). Protein extraction was performed using radioimmune precipitation assay buffer followed by quantification using the DC Protein Assay kit (Bio-Rad). Approximately 40–50 μg was loaded onto an SDS-polyacrylamide 17.5% gel (30% acrylamide, 0.2% bisacrylamide) (5% stacking gel). The running buffer (1×) was adjusted to pH 8.3 before use, and the gel was run at 100 V for ∼15–17 h. Transfer was performed using nitrocellulose membranes (Bio-Rad) and the OwlTM HEP Series Semidry Electrophoresis System for at least 3 h. The membrane was dried at 37 °C for 15 min followed by rehydration with methanol. Membrane dissolution was carried out by addition of 8 mg/ml digitonin (Sigma), and recovered pellets were resuspended in aminocaproic buffer (1.5 M aminocaproic acid and 50 mM Bis-Tris) containing protease inhibitors. Approximately 100 μg of protein was resuspended in aminocaproic buffer and treated with digitonin at a 1:8 ratio (protein:digitonin) (Calbiotech) for 20 min. Recovered supernatant was mixed with 0.5% SERVA Blue G dye (5% SERVA Blue G (w/v), 0.5 mM EDTA, 50 mM Bis-Tris, 750 mM aminocaproic buffer) before loading. 15–30 μg was loaded on a gel. BN-PAGE analysis was carried out in precast 3–12% Bis-Tris blue native gels (Invitrogen). 1× blue cathode buffer (10 mM Tricine, 3 mM Bis-Tris-Cl, pH 7.0, 0.004% (w/v) SERVA Blue G dye) was used to fill the inner chamber, and 1× anode buffer (50 mM Bis-Tris, pH 7.0) was used for the outer chamber. Samples were run at 100 V for 1 h at 4 °C after which the 1× blue cathode buffer was replaced with 1× colorless cathode buffer (10 mM Tricine, 3 mM Bis-Tris-Cl, pH 7.0), and the gel was run at 8 mA for 4 h. Gels were transferred to polyvinylidene difluoride membranes overnight at 75 V at 4 °C. Membranes were dried at 37 °C for 15 min followed by rehydration with methanol. Membrane blocking was carried out in 5% milk in PBST for 4 h before immunoblotting.

**SDS-PAGE and immunoblotting**

Steady-state protein levels were measured in mitochondrially enriched fraction as described previously or in total protein homogenates. Approximately 20–40 μg of protein was mixed with Laemmli buffer (Bio-Rad) supplemented with 5% mercaptoethanol and denatured for 15 min at 65 °C. Samples were separated on 4–20% or 10% SDS-polyacrylamide gels and transferred to polyvinylidene difluoride membranes. Membranes were blocked with 5% milk in 0.1% Tween 20, PBS (PBST) for 1 h and subsequently incubated with specific primary antibodies overnight at 4 °C. The antibodies used included goat polyclonal to MTFMT (T-12) at 1:500 obtained from Santa Cruz Biotechnology (sc-137618), rabbit anti-actin at 1:1000 from Sigma, (A2006), and mouse anti-TIM23 at 1:1000 BD Biosciences (611222). From Abcam, we used mouse monoclonal to MTCO1 at 1:1000 (ab14705), mouse monoclonal to ATP5A at 1:1000 (ab14748), mouse monoclonal to NDUFA9 at 1:1000 (ab14713), mouse monoclonal to SDHA at 1:1000 (ab14715), mouse monoclonal to NDUF8 at 1:1000 (ab110242), mouse monoclonal to UQRC1 at 1:2000 (ab110252), mouse monoclonal to COIV at 1:2000 (ab33985), and mouse monoclonal to vinculin at 1:5000 (ab18058).

Secondary antibodies used were horseradish peroxidase–conjugated anti-mouse at 1:5000, anti-rabbit at 1:3000, and anti-goat at 1:5000 (Santa Cruz Biotechnology) or IRDye 800–conjugated anti-mouse IgG (610-732-124) and IRDye 700–conjugated anti-rabbit IgG (610-430-002) (Rockland). Signal was detected by chemiluminescence using the Super Signal West Pico reagent or by scanning using the Odyssey IR Imaging System.

**BN-PAGE analysis**

BN-PAGE analysis was performed as described previously (31). Approximately four T-75 flasks were grown to 90% confluence. Cell pellets were collected after trypsin digestion. Membrane dissolution was carried out by addition of 8 mg/ml digitonin (Sigma), and recovered pellets were resuspended in aminocaproic buffer (1.5 M aminocaproic acid and 50 mM Bis-Tris) containing protease inhibitors. Approximately 100 μg of protein was resuspended in aminocaproic buffer and treated with digitonin at a 1:8 ratio (protein:digitonin) (Calbiotech) for 20 min. Recovered supernatant was mixed with 0.5% SERVA Blue G dye (5% SERVA Blue G (w/v), 0.5 mM EDTA, 50 mM Bis-Tris, 750 mM aminocaproic buffer) before loading. 15–30 μg was loaded on a gel. BN-PAGE was carried out in precast 3–12% Bis-Tris blue native gels (Invitrogen). 1× blue cathode buffer (10 mM Tricine, 3 mM Bis-Tris-Cl, pH 7.0, 0.004% (w/v) SERVA Blue G dye) was used to fill the inner chamber, and 1× anode buffer (50 mM Bis-Tris, pH 7.0) was used for the outer chamber. Samples were run at 100 V for 1 h at 4 °C after which the 1× blue cathode buffer was replaced with 1× colorless cathode buffer (10 mM Tricine, 3 mM Bis-Tris-Cl, pH 7.0), and the gel was run at 8 mA for 4 h. Gels were transferred to polyvinylidene difluoride membranes overnight at 75 V at 4 °C. Membranes were dried at 37 °C for 15 min followed by rehydration with methanol. Membrane blocking was carried out in 5% milk in PBST for 4 h before immunoblotting.

**Acid-urea PAGE and Northern blot analysis**

Acid-urea PAGE and preparation of samples were performed according to Köhrer and Rajbhandary (32) with slight modifications. In brief, cells were grown in a T150 flask to 90% confluence. Cell pellets were collected after trypsin digestion. For total RNA extraction, the cell pellet was resuspended in TRIzol (Invitrogen), 1/10 volume of sodium acetate buffer (0.3 M sodium acetate, pH 4.5–5.0, 10 mM Na2EDTA) and acid-washed glass beads (0.5-mm diameter; Sigma) were added, and RNA was extracted following Invitrogen’s instructions for TRIzol. The RNA was precipitated with ethanol and recovered by centrifugation at 12,000 × g for 15 min at 4 °C, and the pellet was
washed twice with 70% ethanol; finally dissolved in 20–50 µl of 10 mM sodium acetate, pH 4.5–5.0; and stored at −80 °C until further use. Aminoacyl-tRNAs and formyl aminoacyl-tRNAs were decyaclated by base treatment (alkaline treatment) in 0.1 M Tris-HCl, pH 9.5, at 65 °C for 5 min followed by incubation at 37 °C for 1 h. Aminoacyl-tRNAs were selectively decyaclated by treatment with copper sulfate as described (33). Treated RNAs from Mfmt control and Mfmt-KO cells were separated by acid-urea PAGE as described previously with modifications (9). Briefly, 0.1 A₂₆₀ unit of each RNA sample was loaded onto a 6.5% polyacrylamide gel containing 7 M urea and 0.2 M sodium acetate, pH 5.0. The gel was run in the cold room at 500 V (~12 V/cm) for ~70 h. Individual tRNAs were detected by Northern blotting using the following hybridization probes: 5′-TAG- TACGGGAAGGGTATAA-3′ (mitochondrial tRNA⁰⁰Met) and 5′-TTCCACTGCAACCACACTGCT-3′ (cytoplasmic initiator tRNA⁰⁰Met). Northern blot images were quantified using Image Studio™ Lite software (LI-COR Biosciences).

Mitochondrial bioenergetics

Approximately 2 × 10⁵ cells were seeded in a Seahorse culture plate (3 wells/cell line), and incubated in a 37 °C in a 5% CO₂ humidified atmosphere for 24 h. The cell culture medium from the cell plates was replaced the following day with 175 µl/well prewarmed low-buffered serum-free Seahorse medium supplemented with glucose (2 mM), sodium pyruvate (1 mM), and glucose (10 mM) and incubated at 37 °C in a CO₂-free incubator for 45 min to allow the temperature and pH of the medium to reach equilibrium before the first rate measurement. The pH of the medium was then adjusted to 7.4 with 1 M NaOH. For the mitochondrial respiration rate, the OCR was analyzed in response to oligomycin (1 µM), fluoro-carbonyl cyanide phenylhydrazone (1 µM), and rotenone plus antimycin A (all Sigma) (1 µM). The oxygen consumption rate was used to determined basal respiration, ATP-linked respiration, proton leak, maximum respiratory capacity, spare respiratory capacity, and non-mitochondrial respiration. For the glycolysis assay, the ECAR was measured by monitoring changes in pH in intact cells after sequential addition of glucose (10 mM), oligomycin (1 µM), and the inhibitor of the hexokinase 2-deoxy-D-glucose (75 mM). We measured glycolysis and glycolytic capacity after the addition of oligomycin and estimated the glycolytic reserve as well as the nonglycolytic acidification after the addition of 2-deoxy-D-glucose. All calculations were performed according to the manufacturer’s parameter guidelines. Measurement of protein concentration was performed at the end of each run to normalize OCR and ECAR by protein content using the Lowry assay (Bio-Rad).

Activity in gel (BN-PAGE)

Approximately 60 µg of protein pretreated with mild digitonin were used for BN-PAGE as described above. For complex I activity, the gel was incubated in 0.1 M Tris-HCl, pH 7.4, containing 1 mg/ml nitro blue tetrazolium and 0.14 mM NADH at room temperature. For complex IV activity, the gel was incubated in 1.54 mM diaminobenzidine tetrahydrochloride dissolved in 50 mM phosphate buffer, pH 7.4. Both reactions were incubated at 37 °C for at least 30 min and stopped when the brown color for complex IV activity and blue-purple color for complex I activity appeared.

Statistical analysis

Statistical significance was analyzed using GraphPad software. Two-way repeated-measures analysis of variance (ANOVA) followed by Bonferroni post hoc comparison was performed to analyze replicate means and evaluate interaction among the different technical experiments. Two-tailed unpaired Student’s t test was also used to identify statistically significant differences between groups. p < 0.05 was considered significant. Experimental results are shown as mean ± S.D.
