Background: The calcium-sensing receptor (CaSR) is a key mediator of Ca$^{2+}$ homeostasis in vivo.

Results: An L-Phe binding site at the CaSR hinge region globally enhances its cooperative activation by Ca$^{2+}$.

Conclusion: Communication between the binding sites for Ca$^{2+}$ and L-Phe is crucial for functional cooperativity of CaSR-mediated signaling.

Significance: The results provide important insights into the molecular basis of Ca$^{2+}$ sensing by the CaSR.

Functional positive cooperative activation of the extracellular calcium ([Ca$^{2+}$]$_i$)-sensing receptor (CaSR), a member of the family C G protein-coupled receptors, by [Ca$^{2+}$]$_o$ or amino acids elicits intracellular Ca$^{2+}$ ([Ca$^{2+}$]$_i$) oscillations. Here, we report the central role of predicted Ca$^{2+}$-binding site 1 within the hinge region of the extracellular domain (ECD) of CaSR and its interaction with other Ca$^{2+}$-binding sites within the ECD in tuning functional positive homotropic cooperativity caused by changes in [Ca$^{2+}$]$_o$. Next, we identify an adjacent L-Phe-binding pocket that is responsible for positive heterotropic cooperativity between [Ca$^{2+}$]$_o$ and L-Phe in eliciting CaSR-mediated [Ca$^{2+}$]$_i$ oscillations. The communication between Ca$^{2+}$ and an amino acid globally enhances functional positive homotropic cooperative activation of CaSR in response to [Ca$^{2+}$]$_o$ signaling by positively impacting multiple [Ca$^{2+}$]$_o$-binding sites within the ECD. Elucidation of the underlying mechanism provides important insights into the longstanding question of how the receptor transduces signals initiated by [Ca$^{2+}$]$_o$ and amino acids into intracellular signaling events.

It has long been recognized that Ca$^{2+}$ acts as a second messenger that is released from intracellular stores and/or taken up from the extracellular environment in response to external stimuli to regulate diverse cellular processes. The discovery of the parathyroid Ca$^{2+}$-sensing receptor (CaSR) by Brown et al. (1) has established a new paradigm of Ca$^{2+}$ signaling. In addition to its known role as a second messenger, extracellular Ca$^{2+}$ can function as a first messenger by CaSR-mediated triggering of multiple intracellular signaling pathways, including activation of phospholipases C, A$_2$, and D, and various mitogen-activated protein kinases (MAPKs), as well as inhibition of cyclic adenosine monophosphate (cAMP) production (2–7). This receptor is present in the key tissues involved in Ca$^{2+}$ homeostasis (e.g., parathyroid, kidney, and bone) and diverse other nonhomeostatic tissues (e.g., brain, skin, etc.) (8–11). CaSR consists of a large N-terminal extracellular domain (ECD) (~600 residues) folded into a Venus flytrap motif, followed by a seven-pass transmembrane region and a cytosolic C terminus. The ECD has been shown to play an important role in the cooperative response of the CaSR to [Ca$^{2+}$]$_o$. Elevations in [Ca$^{2+}$]$_o$ activate the CaSR, evoking increases in the intracellular Ca$^{2+}$ concentration ([Ca$^{2+}$]$_i$), producing [Ca$^{2+}$]$_i$ oscillations, modulating the rate of parathyroid hormone secretion, and regulating gene expression (3, 12–14). The pattern of [Ca$^{2+}$]$_i$ oscillations is one of the most important signatures reflecting the state of CaSR activity.

More than 200 naturally occurring mutations have been identified in the CaSR that either inactivate the receptor (reducing sensitivity to [Ca$^{2+}$]$_o$), leading to familial hypocalciuric hypercalcaemia or neonatal severe hyperparathyroidism, or activate it (increasing sensitivity to [Ca$^{2+}$]$_o$), thereby causing autosomal dominant hypoparathyroidism (15–17). Several of these naturally occurring mutations of CaSR exhibit altered functional cooperativity (15).

Functional cooperativity of CaSR (i.e., based on biological activity determined using functional assays rather than a direct binding assay), particularly the functional positive homotropic cooperative response to [Ca$^{2+}$]$_o$, is essential for the ability of the receptor to respond over a narrow physiological range of [Ca$^{2+}$]$_o$ (1.1–1.3 mM) (3). CaSR has an estimated Hill coefficient of 3–4 for its regulation of processes such as activating intracellular Ca$^{2+}$ signaling and inhibiting parathyroid hormone release. Under physiological conditions, L-amino acids,
especially aromatic amino acids (e.g., L-Phe), as well as short aliphatic and small polar amino acids (18), potentiate the high [Ca\(^{2+}\)]\(_{o}\)-elicited activation of the CaSR by altering the EC\(_{50}\) values required for [Ca\(^{2+}\)]\(_{o}\)-evoked [Ca\(^{2+}\)] responses and its functional cooperativity (19, 20). In aggregate, the levels of amino acids in human serum in the fed state are close to those activating the CaSR in vitro (19, 21) and can further enhance functional cooperativity via positive heterotropic cooperativity. Recently, several groups have reported that the CaSR in cells within the lumen of the gastrointestinal tract is activated by L-Phe and other amino acids, which have long been recognized as activators of key digestive processes. Hence, the CaSR enables the tract to monitor events relevant to both mineral ion and protein/amino acid metabolism in addition to the sensing capability of CaSR in blood and other extracellular fluids (19, 22, 23). Glutathione and its \(\gamma\)-glutamylpeptides also allosterically modulate the CaSR at a site similar to the L-amino acid-binding pocket but with over 1,000-fold higher potencies (20, 24). Thus, CaSR is essential for monitoring and integrating information from both mineral ions/nutrients/polyamines in blood and related extracellular fluids. Nevertheless, we still lack a thorough understanding of the molecular mechanisms by which CaSR is activated by [Ca\(^{2+}\)]\(_{o}\) and amino acids, which, in turn, regulate CaSR functional positive cooperativity. In addition, in a clinical setting, the molecular basis for the alterations in this cooperativity caused by disease-associated mutations is largely unknown because of the lack of knowledge of the structure of this receptor and its weak binding affinities for [Ca\(^{2+}\)]\(_{o}\) and amino acids (13, 15, 25, 26).

In the present study, we use two complementary approaches—monitoring [Ca\(^{2+}\)] oscillations in living cells and performing molecular dynamics (MD) simulations—to provide important insights into how the CaSR functions and the behavior of the receptor at the atomic level. We first demonstrate that the molecular connectivity between [Ca\(^{2+}\)]\(_{o}\)-binding sites that is encoded within key Ca\(^{2+}\)-binding site 1 in the hinge region of the CaSR ECD is responsible for the functional positive heterotropic cooperativity in the CaSR response to [Ca\(^{2+}\)]\(_{o}\). We further identify an L-Phe-binding pocket adjacent to Ca\(^{2+}\)-binding site 1. We show that occupancy of this binding pocket by L-Phe is essential for functional positive heterotropic cooperativity by virtue of its having a marked impact on all five of the predicted Ca\(^{2+}\)-binding sites in the ECD with regard to [Ca\(^{2+}\)]\(_{o}\)-evoked [Ca\(^{2+}\)] signaling. Furthermore, with MD simulations, we show that the simulated motions of Ca\(^{2+}\)-binding site 1 are correlated with those of the other predicted Ca\(^{2+}\)-binding sites. Finally, the dynamic communication of L-Phe at its predicted binding site in the hinge region with the CaSR Ca\(^{2+}\)-binding sites not only influences the adjacent [Ca\(^{2+}\)]\(_{o}\) binding site 1 but also globally (i.e., by exerting effects widely over the ECD) enhances cooperative activation of the receptor in response to alterations in [Ca\(^{2+}\)]\(_{o}\).

### MATERIALS AND METHODS

#### Computational Prediction of L-Phe-binding Site and Ca\(^{2+}\)-Binding Sites from a Model Structure—The structure of the extracellular domain of CaSR (residues 25–530) was modeled based on the crystal structure of metabotropic glutamate recep-

- \[ \Delta S = \frac{[M]^n}{K_d^n} + [M]^n \] (Eq. 1)
L-Phe and Ca\textsuperscript{2+} Promote CaSR Functional Positive Cooperativity

where $\Delta S$ is the total signal change in the equation and $[M]$ is the free ligand concentration.

**MD Simulation and Correlation Analysis Using Amber**—MD simulation provides an approach complementary to the experiments in live cells for understanding biomolecular structure, dynamics, and function. The initial coordinates for all the simulations were modeled from the 2.20 Å resolution x-ray crystal structure of mGluR1 with Protein Data Bank code 1EWK (31). The AMBER suite of programs (32) was used to carry out all of the simulations in an explicit TIP3P water model (33), using the modified version of the all-atom Cornell et al. (34) force field and the reoptimized dihedral parameters for the peptide $\omega$-bond (35). An initial 2-ns simulation was performed using NOE restraint during the equilibration to reorient the side chains residues in the Ca\textsuperscript{2+}-binding site, but no restraints were used during the actual simulation. A total of three MD simulations were carried out for 50 ns each on the apo-form and ligand-loaded forms. During the simulations, an integration time step of 0.002 ps was used to solve Newton’s equation of motion. The long range electrostatic interactions were calculated using the particle mesh Ewald method (36), and a cutoff of 9.0 Å was applied for nonbonded interactions. All bonds involving hydrogen atoms were restrained using the SHAKE algorithm (37). The simulations were carried out at a temperature of 300 K and a pressure of 1 bar. A Langevin thermostat was used to regulate the temperature with a collision frequency of 1.0 ps$^{-1}$. The trajectories were saved every 500 steps (1 ps). The trajectories were analyzed using the ptraj module in Amber 10.

**Accelerated Molecular Dynamics Simulation**—Accelerated MD was carried out on the free CaSR ECD using the Rotatable accelerated Molecular Dynamics, (RaMD) method (38) implemented in a pmemd module of AMBER on the rotatable torsion. A boost energy, $E_b$, of 2,000 kcal/mol was added to the average dihedral energy, and a tuning parameter, $\alpha$, of 200 kcal/mol was used. The dual boost was also applied to accelerate the diffusive and solvent dynamics as previously described (39). The simulation conditions were similar to that of the normal MD simulations above. Principal component analysis was carried out on the trajectories using the ptraj module in AMBER. The directions of the eigenvectors for the slowest modes were visualized using the Interactive Essential Dynamics plug-in (40).

**Docking Studies of Phe, Asp, and Glutathione**—The binding energies for the ligands were calculated using an ensemble-docking method and Autodock vina (28). The ensemble of conformations of CaSR was generated using molecular dynamics simulations as described above. Gasteiger charges were assigned to the ligands and CaSR using the Autodock ADT program. The ligands were flexible during docking to each conformation of CaSR using the following parameters: the grid spacing was 1.0 Å; the box size was 25 Å in each dimension, and the center of the box was chosen as the center of the active site of CaSR, with a large enough space to sample all possible ligand conformations within the box. The maximum number of binding modes saved was set to 10. The conformation with the lowest binding energy was used and assumed to be the best binder. Distributions of the binding energies for each ligand were calculated based on the lowest binding energy of each ligand to each conformation in the ensemble of CaSR conformations.

**Principal Component Analysis**—Using the ptraj module of AMBER 10, principal component analysis (PCA) (41, 42) was performed on all the atoms of the residues that are 5 Å away from site 1 of CaSR ECD. The covariance matrix of the $x$, $y$, and $z$ coordinates of all the atoms obtained from each snapshot of the combined trajectories of the ligand-free CaSR ECD, the Ca\textsuperscript{2+}-loaded form, the form loaded with only L-Phe, and the form loaded with both Ca\textsuperscript{2+} and L-Phe were calculated. The covariance matrix was further diagonalized to produce orthonormal eigenvectors and their corresponding eigenvalues, ranked on the basis of their corresponding variances. The first three eigenvectors, the principal components that contributed the majority of all the atomic fluctuations, were used to project the conformational space onto them, i.e., along two dimensions.

**Statistics**—The data are presented as means ± S.E. for the indicated number of experiments. Statistical analyses were carried out using the unpaired Student’s t test when two groups were compared. A $p$ value of $< 0.05$ was considered to indicate a statistically significant difference.

**RESULTS**

**Molecular Connectivity among Predicted Calcium-binding Sites Is Required for Functional Positive Cooperativity of CaSR**—It has been documented that in several regions of the CaSR and mGluRs, the amino acid residues are highly conserved (43). Those conserved elements provide a structural framework for the modeling of the CaSR ECD. Among all the available crystal structures of the mGluRs, studies on mGluR1 give concrete structural information about ligand-free as well as various ligand-bound forms of the receptor. Moreover, CaSR and mGluR1 share similar signaling pathways and can form heterodimers with one another either in vivo or in vitro (44). Thus, the crystal structures of mGluR1 were employed for modeling the CaSR ECD. By using our own computational algorithms, we previously identified five putative Ca\textsuperscript{2+}-binding sites in the modeled CaSR ECD (Fig. 1) (25, 26, 45). Among these, site 1 is located in the hinge region between the two lobes in the Venus flytrap motif. Among 34 newly identified naturally occurring missense mutations within the ECD, 18 are located within 10 Å of one or more of the predicted Ca\textsuperscript{2+}-binding sites (15). Interestingly, a few disease-associated human mutations severely impair the functional cooperativity of CaSR (46).

Functional positive homotropic cooperativity here refers to [Ca\textsuperscript{2+}]\textsubscript{i}-induced changes in CaSR activity that can be ascribed to interactions between the five predicted Ca\textsuperscript{2+}-binding sites, which are located in different regions of the ECD (47–49). To understand the observed cooperativity and the origin of changes in cooperativity caused by disease-associated mutations at the atomic level, we have carried out MD simulations on the modeled CaSR ECD to predict correlated motions. MD simulation provides an approach complementary to the experiments in live cells for understanding biomolecular structure, dynamics, and function (50). We calculated the cross-correlation coefficients of each residue with those of all of the other residues in the CaSR ECD from the simulations (“Material and Methods”). Fig. 1 (lower right panel) shows the normalized correlation matrix map of both negative (blue) and positive (red) correlated motions between each pair of residues. Negative and
L-Phe and Ca\textsuperscript{2+} Promote CaSR Functional Positive Cooperativity

FIGURE 1. Delineating the molecular connectivity associated with functional positive homotropic and positive heterotropic cooperativity within the CaSR ECD by molecular modeling of L-Phe- and Ca\textsuperscript{2+}-binding sites. The model structure of the ECD of CaSR was based on the mGluR1 crystal structure (Protein Data Bank code 1ISR) and was generated using MODELER 9v4 and PyMOL. Upper right panel, five predicted Ca\textsuperscript{2+}-binding sites are located in the ECD and are highlighted with frames. Residues involved in Ca\textsuperscript{2+}-binding are shown in yellow. Correlated motions among Ca\textsuperscript{2+}-binding site 1 and the other Ca\textsuperscript{2+}-binding sites are shown by lines of various colors. Upper panel, a zoomed in view of site 1, residues involved in the predicted L-Phe-binding site are highlighted in pink, Red, Ca\textsuperscript{2+}; yellow, L-Phe. Lower panel, the correlation map of the modeled CaSR ECD structure. The correlation map is depicted based on MD simulations. The strongest negative correlation is given the value $-1$, whereas the strongest positive correlation is defined as $+1$. The circles on the correlation map reflect the movements between different binding sites (corresponding to the correlated motions in the upper right panel) during the MD simulation.

positive correlated motions indicate movements in the opposite direction or in the same direction, respectively. Positive correlations occur between groups of residues if they are within the same domain or directly interact with each other. Fig. 1 shows strong correlations among residues from Ser\textsuperscript{169} to Ala\textsuperscript{324}. Notably, the negative correlated motions between residues Lys\textsuperscript{87}–Leu\textsuperscript{125} and residues Ser\textsuperscript{240}–Ala\textsuperscript{306} suggest that the two lobes undergo a dynamic change similar to that of mGluR1 upon interactions with its ligands. Closer analysis indicates that residues involved in Ca\textsuperscript{2+}-binding site 1 exhibit negative correlations with residues in sites 2–5 (Table 1).

We then predicted a putative amino acid-binding site in the modeled CaSR based on its sequence homology to mGluR1 and its ligand-loaded form using AutoDock-Vina (28). As shown in Fig. 1 (upper left panel), this potential amino acid-binding pocket, formed by residues Lys\textsuperscript{87}, Leu\textsuperscript{125}, Trp\textsuperscript{79}, Thr\textsuperscript{145}, Gly\textsuperscript{146}, Ser\textsuperscript{169}, Ser\textsuperscript{170}, Ile\textsuperscript{187}, Tyr\textsuperscript{218}, Ser\textsuperscript{272}, His\textsuperscript{413}, and Arg\textsuperscript{415}, partially overlaps Ca\textsuperscript{2+}-binding site 1 in the modeled CaSR ECD. Its predicted location is consistent with previous functional studies, suggesting important roles for Ser\textsuperscript{170} and Thr\textsuperscript{145} in amino acid-potentiated intracellular calcium responses (51–53). This L-Phe-binding site is also located within the hinge region of the ECD of CaSR with a relatively localized configuration during MD simulations. Other Ca\textsuperscript{2+}-binding sites (sites 2–5) are more than 10 Å away from the L-Phe-binding site (26). This partial colocalization of predicted Ca\textsuperscript{2+}-binding site 1 and the amino acid-binding site at the hinge domain in the ECD of the CaSR is also observed in other members of the family C G protein-coupled receptors (GPCRs), including mGluRs and taste receptors, which share some degree of sequence similarity with the CaSR (Fig. 2a) (1, 5, 10, 16, 54–56). The calculated free energies for the binding of CaSR with various ligands (in the order of glutathione > L-Phe > L-Asp) is in excellent agreement with the experimental results obtained by determining the EC\texttextsubscript{50} of intracellular Ca\textsuperscript{2+} responses to the same ligands (Fig. 2b) (19).

We define functional positive heterotropic cooperativity as that which occurs when the functional positive cooperative effect of interaction with one ligand (e.g., Ca\textsuperscript{2+}) affects the functional response resulting from interaction of a different ligand with the protein (i.e., an aromatic amino acid) (57). This term can be applied in the case of CaSR when it simultaneously senses Ca\textsuperscript{2+} and L-Phe. We have also observed greater correlated motions among the multiple Ca\textsuperscript{2+}-binding sites after docking both Ca\textsuperscript{2+} and L-Phe compared with docking of L-Phe alone to the ECD domain of the CaSR (Fig. 2c). Taking these results together, we propose that there is molecular connectivity centered at predicted calcium-binding site 1 that plays an essential role in regulating the correlated motions among the multiple Ca\textsuperscript{2+}-binding sites. Further communication of this site with the amino acid-binding site is likely to mediate functional heterotropic cooperativity of CaSR-mediated signaling, as shown later.

Functional Positive Homotropic Cooperativity among Ca\textsuperscript{2+}-binding sites—Given that it is not readily possible to perform radioligand binding assays on CaSR because of its low affinity for its ligands, especially Ca\textsuperscript{2+} (e.g., mG K\textsubscript{0}), as well as difficulty in purification of CaSR, we monitored [Ca\textsuperscript{2+}]\textsubscript{i} responses both by using a cuvette population assay and by monitoring [Ca\textsuperscript{2+}]\textsubscript{i} oscillations using single-cell imaging to determine functional cooperativity of CaSR. HEK293 cells transfected with WT CaSR exhibited sigmoidal concentration response curves for [Ca\textsuperscript{2+}]\textsubscript{o}-evoked [Ca\textsuperscript{2+}]\textsubscript{i} responses (as monitored by changes in the ratio of fluorescence at 510 nm when excited at 340 or 380 nm) during stepwise increases in [Ca\textsuperscript{2+}]\textsubscript{o} with a Hill coefficient of 3.0 ±

### Functional Positive Cooperativity among Ca\textsuperscript{2+} and L-Phe

The cross-correlation coefficients of each residue to all of the other residues of the modeled CaSR ECD structure after docking with calcium were calculated from the experimental results obtained by determining the EC\texttextsubscript{50} of intracellular Ca\textsuperscript{2+} responses to the same ligands (Fig. 2b) (19).

The correlation map is depicted based on MD simulations. The strongest negative correlation is given the value $-1$, whereas the strongest positive correlation is defined as $+1$. The circles on the correlation map reflect the movements between different binding sites (corresponding to the correlated motions in the upper right panel) during the MD simulation.
0.1 and an EC$_{50}$ of $2.9 \pm 0.2$ mM. This result suggests strong positive homotropic cooperativity within the five predicted Ca$^{2+}$-binding sites of the CaSR (Fig. 3). The sensitivity to agonist was assessed using the [Ca$^{2+}$]$_o$ at which cells began to show Ca$^{2+}$ oscillations and the frequency of the oscillations at the respective levels of [Ca$^{2+}$]$_o$, at which more than 50% of the cells started to oscillate. To seek the key determinants underlying the observed functional positive homotropic cooperativity, mutations were introduced into the various predicted Ca$^{2+}$-binding sites of the CaSR by site-directed mutagenesis. The mutated receptors exhibited impaired Ca$^{2+}$ sensing capabilities with altered oscillation patterns in single-cell studies and higher EC$_{50}$ values compared with WT CaSR in population studies (Tables 2 and 3 and Figs. 3 and 4). Such population studies were also reported in our previous studies (25, 26). Results from Western blot and immunofluorescence staining using an anti-CaSR antibody indicated essentially equivalent expression of WT CaSR as well as its variants on the cell surface (Fig. 5). As shown in Fig. 3a, the level of [Ca$^{2+}$]$_o$ required to initiate oscillations in mutant E297I at predicted Ca$^{2+}$-binding site 1 or D215I at site 2 increased markedly from $3.0 \pm 0.1$ mM to $17.0 \pm 0.4$ and $13.9 \pm 0.2$ mM, respectively (n > 30, p < 0.05). Correlating well with these results, the two mutants had significantly impaired responses at different levels of [Ca$^{2+}$]$_o$ in the single-cell assay (Fig. 6c and Table 2). Meanwhile, L-Phe also increased the oscillation frequency from 1.5 ± 0.1 to 2.2 ± 0.2 peaks/min (n > 30, p < 0.05) in the presence of 3.0 mM [Ca$^{2+}$]$_o$ in the single-cell assay (Fig. 6c and Table 2). We then performed detailed analyses to understand the role of residues in the modeled L-Phe-binding site in the functional positive heterotropic cooperativity contributed by L-Phe (Fig. 6 and Table 4). Five of 12 residues located within 5 Å of the modeled L-Phe-binding site exhibited impaired L-Phe-sensing ability. Mutants L51A and S170T exhibited impaired L-Phe sensing capability as indicated by the absence of any change in the starting point (Fig. 6b) as well as constant oscillatory frequencies (~1.7 and 1.4 peaks/min) in the presence of L-Phe (Fig. 6c).
whereas they maintained relatively unaltered calcium-sensing functions. Consistent with the single-cell assay results, cell population studies revealed that the EC_{50} values of L51A, S170T, and Y218Q remained the same with or without l-Phe (Fig. 6a) (the effect of l-Phe on S170T has previously been reported by Zhang et al. (51) in a cell population assay). The addition of 5 mM l-Phe lowered the [Ca^{2+}]_o required to initiate oscillations in cells transfected with mutations S272A or T145A but failed to increase the oscillatory frequency at 2.5 mM [Ca^{2+}]_o (the level at which the majority of the cells began to oscillate), nor did it reduce the EC_{50} (Table 4 and Fig. 7). Tyr^{218} is predicted to be involved in binding of both l-Phe in its binding pocket and of Ca^{2+} in site 1. Indeed, the mutation Y218Q largely disrupted the functional positive homotropic cooperativity with transformation of the single cooperative response to [Ca^{2+}]_o, of the WT CaSR to a biphonic process in the cell population assay. Y218Q also exhibited less sensitivity to [Ca^{2+}]_o, because [Ca^{2+}]_o oscillations did not start until [Ca^{2+}]_o was increased to more than 10 mM, reflecting its role in this Ca^{2+}-binding site. Of note, however, addition of 5 mM l-Phe failed to restore the calcium sensitivity of this mutant as manifested by an unchanged oscillation pattern. An oscillation frequency of ∼1.5 peaks/min was observed at 20 mM [Ca^{2+}]_o both with and without l-Phe for this mutant. In contrast, mutations such as K47A, Y63I, W70L, G146A, I162A, S169A, I187A, H413L, and R415A did not abrogate the positive allosteric effect of 5 mM l-Phe (Table 5). Taken together, these results suggest that residues located at the predicted l-Phe-binding site, including Leu^{51}, Thr^{145}, Ser^{170}, Ser^{272}, and Tyr^{218}, play key roles in sensing l-Phe.

### Global Functional Positive Heterotropic Cooperative Tuning by l-Phe of the Positive Homotropic Cooperative Response of CaSR to [Ca^{2+}]_o—The sensing of l-Phe at the hinge region adjacent to site 1 has marked global (i.e., extending widely over the ECD) effects on the five predicted Ca^{2+}-binding sites predicted earlier, which are spread over several different locations in the CaSR ECD. Interestingly, addition of 5 mM l-Phe significantly rescued the [Ca^{2+}]_o responses of the two mutants, E297I and D215I, in sites 1 and 2, respectively, that exhibited disrupted cooperativity. Notably, l-Phe converted the biphonic Ca^{2+}-response curve for E297I back to a uniphonic curve (Fig. 8). Fig. 8 shows that their starting points for [Ca^{2+}]_o-initiated oscillations were reduced from 17.0 ± 0.4 to 7.3 ± 0.2 mM (E297I) and from 13.9 ± 0.2 to 6.7 ± 0.3 mM (D215I), respectively, in the presence of l-Phe (Table 2). Both of the mutants exhibited more than 2-fold shifts in their starting points in the presence of l-Phe. The frequencies of their oscillations increased to more than 2 peaks/min in both cases compared

*a Indicates significance with respect to the corresponding experiment in the same mutant without l-Phe (p < 0.05).

*b Indicates significance with respect to wild type CaSR without l-Phe (p < 0.05).
"Materials and Methods." The cells on glass coverslips were then transferred into the cuvette for fluorimetry and exposed to various increases in [Ca$^{2+}$] by stepwise increases in [Ca$^{2+}$] as indicated above the oscillation pattern using a perfusion system until [Ca$^{2+}$] reached a plateau (up to 30 mM [Ca$^{2+}$]). At least 30 cells were analyzed for each mutant. Specifically, the addition of L-Phe decreased their EC$_{50}$ values in the absence of L-Phe; however, the number of peaks/min was recorded at the level of [Ca$^{2+}$] which gave EC$_{50}$ and Hill numbers. The maximum response for each mutant was subtracted from the baseline and normalized to the maximal cumulative [Ca$^{2+}$] response of the WT receptor. The data were obtained from three experiments for each construct.

$^{a}$ Indicates significance with respect to the corresponding mutants in the absence of L-Phe ($p < 0.05$).

$^{b}$ Indicates significance with respect to wild type CaSR in the absence of L-Phe ($p < 0.05$).

FIGURE 4. Individual cellular responses of mutants in calcium-binding sites to the indicated increments of [Ca$^{2+}$] in the presence or absence of L-Phe. a, representative intracellular calcium response from a single cell. Fura-2-loaded HEK293 cells expressing CaSR with mutations in calcium-binding site 3, 4, or 5 were prepared for single-cell experiments. Each experiment with or without 5 mM L-Phe began in the same non-calcium-containing Ringer buffer followed by stepwise increases in [Ca$^{2+}$] as indicated above the oscillation pattern using a perfusion system until [Ca$^{2+}$] reached a plateau (up to 30 mM [Ca$^{2+}$]). At least 30 cells were analyzed for each mutant. b, frequency distribution of the [Ca$^{2+}$] at which CaSR-transfected single HEK293 cells started to oscillate. The cell number percentage is defined as the number of cells starting to oscillate at a given [Ca$^{2+}$]/total cell number showing oscillation pattern $\times 100$. Empty bar, in the absence of L-Phe; black bar, in the presence of 5 mM L-Phe. c, the frequency distribution of the oscillation frequency from single cells was investigated as described before. For experiments without L-Phe, the number of peaks/min was recorded at the level of [Ca$^{2+}$], at which the majority of the cells ($>50\%$) started to oscillate; for experiments with 5.0 mM L-Phe, the frequency was analyzed at the same [Ca$^{2+}$] that was used in the absence of L-Phe. Specifically, the frequency of E224I was studied at 4 mM [Ca$^{2+}$], E353I was analyzed at 5.0 mM [Ca$^{2+}$], and D398A/E399I was investigated at 10.0 mM [Ca$^{2+}$]. Empty bar, in the absence of L-Phe; black bar, in the presence of 5 mM L-Phe.

with the frequencies without L-Phe (Fig. 8c and Table 2). Similarly, the addition of L-Phe decreased their EC$_{50}$ values in the cell population assay (Table 3).

$^{a}$ Indicates significance with respect to the corresponding mutants in the absence of L-Phe ($p < 0.05$).

$^{b}$ Indicates significance with respect to wild type CaSR in the absence of L-Phe ($p < 0.05$).

Mutant E224I at site 3 exhibited increases in the [Ca$^{2+}$] required to initiate [Ca$^{2+}$] oscillations but manifested smaller changes (from 3.0 ± 0.1 to 5.0 ± 0.2 mM [Ca$^{2+}$], $p < 0.05$).
L-Phe and Ca\textsuperscript{2+} Promote CaSR Functional Positive Cooperativity

FIGURE 5. Expression of WT CaSR and its mutants in HEK293 cells. a, Western blot analyses of CaSR and its mutants in transiently transfected HEK293 cells. 40 μg of total protein from cellular lysates were subjected to 8.5% SDS-PAGE. Three characteristic bands are shown in the upper panel, including the top band representing the dimeric receptor, the middle band showing mature glycosylated CaSR monomer (150 kDa), and the lowest band indicating immature glycosylated CaSR monomer (130 kDa). b, quantification of the expression of WT CaSR and its mutants in HEK293 cells. All the bands, including the one indicating dimeric receptor, mature glycosylated monomer and the one showing immature CaSR monomer, were taken into consideration. The internal control GAPDH was used to standardize CaSR expression, and the mutants were further normalized to the WT CaSR expression. c, immunofluorescence analyses of surface expressed WT CaSR and its mutants in HEK293 cells. Immunostaining was done with anti-CaSR monoclonal antibody A7 (70), and detection was carried out with Alexa Fluor 488-conjugated, goat anti-mouse secondary antibody. Red, propidium iodide staining of cell nuclei; green, CaSR. Equivalent expression of WT CaSR as well as its variants on the cell surface suggests that the difference in the Ca\textsuperscript{2+} sensing capabilities among the WT and mutant receptors are due to perturbation of the functions of cell surface receptors, rather than, for example, impaired trafficking of the receptor proteins to the cell surface.

compared with the previous two mutants. Moreover, its elevated EC\textsubscript{50} value obtained in the population study correlated well with results from the single-cell study (Tables 2 and 3), suggesting an impaired ability of this mutant to sense [Ca\textsuperscript{2+}]\textsubscript{o}. However, addition of L-Phe not only significantly decreased the level of [Ca\textsuperscript{2+}]\textsubscript{o} required for initiating oscillations but also increased the oscillation frequency measured at the same level of [Ca\textsuperscript{2+}]\textsubscript{o}. Furthermore, the population assay showed that the EC\textsubscript{50} was reduced, and the maximum response was rescued by 5 mM L-Phe.

Glu\textsuperscript{353} is part of Ca\textsuperscript{2+}-binding site 4 in lobe 2, whereas Asp\textsuperscript{398} and Glu\textsuperscript{399} are involved in site 5 (26). Table 3 and Fig. 4 show that removal of these negatively charged residues at sites 4 and 5 increased the level of [Ca\textsuperscript{2+}]\textsubscript{o} required to initiate [Ca\textsuperscript{2+}] oscillations and also the receptors’ EC\textsubscript{50} values of the mutant receptors. L-Phe at 5 mM was able to enhance the sensitivity of these mutants to [Ca\textsuperscript{2+}]\textsubscript{o} and decrease their EC\textsubscript{50} values. Therefore, as shown in Table 2, not only Ca\textsuperscript{2+}-binding residues adjacent to the predicted L-Phe-binding site (e.g., sites 1 and 2) but also sites farther away from the hinge region exhibited L-Phe-induced decreases in EC\textsubscript{50} and starting point as well as increases in oscillation frequency and Hill coefficient. This result suggests the global nature of the functional positive heterotropic cooperative interaction between L-Phe and extracelular Ca\textsuperscript{2+}.

The Ensemble of Conformations of Calcium- and L-Phe-loaded CaSR ECD Is Distinguishable from the Nonloaded Forms

To provide a more detailed description of the CaSR mechanism of action at the atomic level, we again used MD simulations to analyze the trajectories of these simulations using PCA (“Materials and Methods”), which separates out the protein motions into principal modes ranked according to their relative contributions (41). Projection of the trajectories of the different states of CaSR onto the first three modes, which accounted for the majority of the total fluctuations, is shown in Fig. 9a. The conformations sampled by the Ca\textsuperscript{2+}-free and L-Phe-free forms of the CaSR are distinctly different from those sampled by the Ca\textsuperscript{2+}-loaded and Ca\textsuperscript{2+} and L-Phe-loaded forms of the receptor. Interestingly, the conformations of the L-Phe-loaded and the free forms of CaSR are essentially indistinguishable, as can be seen in Fig. 9a. The results suggest that [Ca\textsuperscript{2+}]\textsubscript{o} shifts the population of conformational ensembles of CaSR to a semi-active ensemble that can subsequently be shifted to an ensemble of more active conformations upon interaction of the receptor with L-Phe. These results are consistent with the experiments described above and suggest that the unbound CaSR does not respond to L-Phe alone, because L-Phe cannot effectively shift the inactive conformations to an active ensemble of conformations. The above results do not rule out the role of conformational selection, which implies the existence of all relevant active and inactive conformations of the receptor before binding, in the mechanism of activation of CaSR, but clearly indicate that the ensembles of active and inactive conformations are distinctly different and that [Ca\textsuperscript{2+}]\textsubscript{o} alone and/or [Ca\textsuperscript{2+}]\textsubscript{o} and L-Phe together are required to shift the population, in agreement with previously well documented experimental results that L-Phe could not activate CaSR at sub-threshold levels of [Ca\textsuperscript{2+}]\textsubscript{o} (below ∼1.0 mM in CaSR-transfected HEK293 cells) (58).

Based on all the experimental results and the directions of the eigenvectors from the long time simulation (Fig. 9b), we propose a model to illustrate the possible mechanism by which Ca\textsuperscript{2+} and L-Phe regulate the function of the CaSR mainly through the molecular connectivity encoded at the hinge region of the ECD of the protein. Our model (Fig. 9c) suggests that a local conformational change upon interaction of the
CaSR with L-Phe might affect the overall conformation of the receptor, thereby influencing the cooperativity between multiple Ca\textsuperscript{2+}/H11001-binding sites and enhancing the overall response of the receptor to Ca\textsuperscript{2+}/H11001.

**DISCUSSION**

Several major barriers have hampered our understanding of how CaSR integrates its activation by two different classes of nutrients, divalent cations and amino acids, to regulate the functional cooperativity of the receptor and of the alterations of this cooperativity caused by disease mutations. These include “invisible” binding pockets for these two key physiological agonists of the CaSR, namely Ca\textsuperscript{2+}/H11001 and amino acids, challenges in obtaining structural information associated with membrane proteins, and the lack of direct binding methods in determining the mechanism underlying cooperative activation of the CaSR by Ca\textsuperscript{2+} and amino acids (13, 19, 59). To overcome these limitations, we have developed several computer algorithms and a grafting approach for identifying and predicting Ca\textsuperscript{2+}/H11001-binding sites in proteins, and we have successfully verified the intrinsic Ca\textsuperscript{2+}/H11001-binding capabilities of predicted Ca\textsuperscript{2+}/H11001-binding sites in the CaSR and mGluR1\textsubscript{a} (25–27, 60).

Our studies, shown in Figs. 1, 3, and 6, suggest that mutations in Ca\textsuperscript{2+}/H11001-binding site 1, such as E2971 and Y218Q, not only disrupt the Ca\textsuperscript{2+} sensing capacity of CaSR but also have an impact on the positive homotropic cooperative interactions of Ca\textsuperscript{2+} with the other Ca\textsuperscript{2+}/H11001-binding sites. The biphasic behavior of these mutants with a large disruption of cooperativity is very similar to our previously reported metal-binding concentration response curves of subdomain 1 and its variants with increases in [Ca\textsuperscript{2+}]\textsubscript{o} (26). Subdomain 1 of CaSR contains a protein sequence encompassing Ca\textsuperscript{2+}/H11001-binding sites 1, 2, and 3, but not

**FIGURE 6. Functional studies of receptors with mutations in L-Phe-binding site in HEK293 cells.**

- **a**, representative oscillation pattern from a single cell. Each experiment with or without 5 mM L-Phe began in Ca\textsuperscript{2+}-free Ringer buffer followed by stepwise increases in [Ca\textsuperscript{2+}]\textsubscript{o} until [Ca\textsuperscript{2+}]\textsubscript{i} reached a plateau (up to 30 mM [Ca\textsuperscript{2+}]\textsubscript{o}).
- **b**, the pattern of [Ca\textsuperscript{2+}] responses in each cell (minimum of 30 cells) was analyzed, and the [Ca\textsuperscript{2+}]\textsubscript{o} at which individual cells started to oscillate was recorded and plotted as a bar chart.
- **c**, the frequency of the oscillation patterns of the individual cells was investigated. For experiments without L-Phe, the number of peaks/min was recorded at the level of [Ca\textsuperscript{2+}]\textsubscript{i} at which the majority of the cells (>50%) started oscillating, although for experiments with 5 mM L-Phe, the frequency was analyzed at the same levels of [Ca\textsuperscript{2+}], as in the corresponding experiments carried out without L-Phe.
- **d**, population assay for [Ca\textsuperscript{2+}]\textsubscript{i} responses of HEK293 cells transiently overexpressing WT CaSR or CaSR mutants L51A or Y218Q using Fura-2 AM during stepwise increases in [Ca\textsuperscript{2+}]\textsubscript{o} from 0.5 to 30 mM. The ratio of the intensity of light emitted at 510 nm upon excitation with 340 or 380 nm was normalized to its maximum response. The [Ca\textsuperscript{2+}]\textsubscript{o} concentration response curves were fitted using the Hill equation.

* Significant difference between cases without L-Phe and with 5 mM L-Phe (p < 0.05).
* Significant difference between mutant receptor and WT CaSR without L-Phe (p < 0.05).

**FIGURE 7. Individual cellular responses of mutants in the L-Phe-sensitive site to the indicated increments of [Ca^2+][rsqb] in the presence or absence of L-Phe.**

HEK293 cells transfected with wild type CaSR or mutants were loaded with Fura-2 AM for 15 min. Each experiment with or without 5 mM L-Phe began in the same non-calcium-containing Ringer buffer followed by stepwise increases in [Ca^2+][rsqb] until Ca^2+ reached a plateau (up to 30 mM) as monitored by changes in the ratio of light emitted at 510 nm following excitation at 340 or 380 nm. At least 30 cells were analyzed for mutants S272A and T145A. Representative cellular responses from a single cell are shown.

Ca^2+/-binding sites 4 and 5. It also exhibits both strong and weak metal-binding components. This strong metal-binding process can be removed by further mutating site 1 (E297I). In contrast, mutations at sites 2 and 3 in subdomain 1 have less impact on the first binding process (26). These experimental results are consistent with molecular dynamics simulation studies carried out here showing that residues located at site 1 have strong correlated motions with other residues involved in sites 2, 3, 4 and 5 (Table 1). The results suggest that the dynamics of site 1 are intrinsically coupled to those of the other binding sites; therefore, any changes in the dynamics of site 1 could affect those of the other sites. The observation of this molecular connectivity and its relationship to positive cooperativity from the molecular dynamics simulations provides a description at the atomic level of the cross-talk between the different sites of the CaSR suggested by the experimental results in live cells.

Here, we have also identified and characterized an L-Phe-binding pocket formed by residues Leu^51, Ser^170, Thr^145, Tyr^218, and Ser^272 that is adjacent to and partially overlaps the key Ca^2+/-binding site 1 at the hinge region of the Venus flytrap of the CaSR. This Ca^2+/-binding site is also conserved in other family C GPCRs, including the mGluR1 Venus flytrap (Fig. 2) (27, 31, 56). Tyr^218 is involved in sensing both Ca^2+ and L-Phe. The aromatic ring from residue Tyr^218 could form delocalized pi bonds with the side chain of L-Phe and the hydrophobic interaction between Leu^51 and L-Phe would further stabilize this interaction. Mutating Ser^170 might interfere with H-bonding of the ligated amino acid to the o-amino group of Ser^170 based on the structure of mGluR1α (53). S170T has been reported by different groups to interfere with the L-Phe sensing ability of CaSR (51, 53). Consideration of the crystal structure of the glutamate-bound form of mGluR1 (31), together with our docking analysis, implies that residues Thr^145 and Ser^272 may not directly participate in the interaction with L-Phe but could possibly interact with L-Phe by ligation of water molecules, which is a relatively weaker type of interaction.

We have observed essentially equivalent expression of WT CaSR as well as its variants on the cell surface (Fig. 5). These data suggest that the difference in the Ca^2+ sensing capacities among the WT and mutant receptors are due to perturbation of the cell surface receptor functions rather than, for example, impaired trafficking of the receptor proteins to the cell surface. L-Phe rescued the calcium responses of the tested mutants located in all five predicted Ca^2+/-binding sites, and it had more dramatic rescuing effects on mutants E297I and D215I compared with the other mutants (Fig. 8d). Thus, the importance of the hinge region, where L-Phe likely interacts with the CaSR ECD, is once again highlighted.

The PCA results suggest that the need for Ca^2+ in initially activating CaSR, as suggested by these experiments, is related to shifting the ensemble of conformations of CaSR from an inactive state to an active state. The activity of the Ca^2+/-loaded form of CaSR is then further enhanced by the binding of L-Phe, which produces an additional change in the ensembles of conformations of CaSR. Therefore, the global modulation of receptor activity by Ca^2+ and L-Phe might be explained by a combination of an induced fit and population shift models (61); that is, the overall structure of the receptor could vary in the equilibrium distributions of conformations that can interchange dynamically in the absence of Ca^2+ and L-Phe. Our experimental results suggest that binding of Ca^2+ at its various sites is associated with motions of these sites that are highly correlated...
**TABLE 5**

Summary of cellular responses from HEK293 cells transiently transfected with WT CaSR or mutants in the predicted L-Phe-sensing site

The intracellular calcium responses of HEK293 cells transiently overexpressing WT CaSR or various mutants potentially involved in the interaction with L-Phe were measured using Fura-2 AM during stepwise increases in [Ca\(^{2+}\)]. The pattern of [Ca\(^{2+}\)] responses in each cell (minimum of 30 cells) was analyzed, and the [Ca\(^{2+}\)], at which CaSR-transfected single HEK293 cells started to oscillate was recorded. For experiments without L-Phe, the number of peaks/min was recorded at the level of [Ca\(^{2+}\)] at which the majority of the cells (>50%) started oscillating, whereas for experiments with 5 mM L-Phe, the frequency was analyzed at the same levels of [Ca\(^{2+}\)], as in the corresponding experiments carried out without L-Phe. Specifically, WT, K47A, G146A, S169A, and H413L were measured at 3.0 mM [Ca\(^{2+}\)]; Y63I and R415A were measured at 3.5 mM [Ca\(^{2+}\)]; E297I and D215I were measured at 0.5 mM [Ca\(^{2+}\)]; and I187A was measured at 10.0 mM [Ca\(^{2+}\)]. [Ca\(^{2+}\)] was plotted against frequency of the oscillation patterns was investigated in more than 30 cells. For experiments without L-Phe, the number of peaks/min was recorded at the level of 50% started oscillating, whereas for experiments with 5 mM L-Phe, the frequency was analyzed at the same levels of [Ca\(^{2+}\)], as in the corresponding experiments carried out without L-Phe. 

![Diagram](image_url)

**FIGURE 8.** [Ca\(^{2+}\)] responses of CaSRs with mutations in the Ca\(^{2+}\)-binding sites stimulated by increasing [Ca\(^{2+}\)] in the presence or absence of 5 mM L-Phe. **a**, [Ca\(^{2+}\)], was monitored in mutants E297I and D215I in the absence or presence of L-Phe. [Ca\(^{2+}\)] was increased stepwise up to 30 mM or until [Ca\(^{2+}\)] reached a plateau. **b**, frequency distribution of [Ca\(^{2+}\)] was monitored in mutants E297I and D215I in the absence or presence of L-Phe. **c**, frequency of the oscillation patterns was investigated in more than 30 cells. For experiments without L-Phe, the number of peaks/min was recorded at the level of [Ca\(^{2+}\)] at which the majority of the cells (>50%) started oscillating, whereas for experiments with 5 mM L-Phe, the frequency was analyzed at the same levels of [Ca\(^{2+}\)], as in the corresponding experiments carried out without L-Phe. **d**, [Ca\(^{2+}\)] responses of HEK293 cells transiently transfected with Ca\(^{2+}\)-binding site-related CaSR mutants using Fura-2 AM during stepwise increases in [Ca\(^{2+}\)], from 0.5 to 30 mM. [Ca\(^{2+}\)], responses were further fitted using the Hill equation. Inset in top panel of **d**, zoomed in view of the binding first phase.

with one another. Consequently, the shift in the ensemble of conformations of CaSR induced by the initial binding of Ca\(^{2+}\) at site 1 will alter the equilibrium population of the unbound conformations of other Ca\(^{2+}\)-binding sites because of their cross-talk with site 1. The binding of Ca\(^{2+}\) to site 1 and the subsequent interaction of CaSR with L-Phe can further shift the conformations of the ECD from one part of the free energy landscape to another. In this way, Ca\(^{2+}\) binding to other sites is more readily favorable. Our findings here also enhance our understanding of the role of Ca\(^{2+}\) in modulating key Ca\(^{2+}\)-
binding proteins, such as calmodulin, to mediate signal transduction via correlated motions among their multiple Ca\(^{2+}\) binding sites, thereby generating cooperative responses with critical biological consequences (62, 63).

The coactivation of CaSR by these two classes of ligands may be particularly important in the gastrointestinal tract, where high concentrations of amino acids resulting from protein digestion would promote activation of the CaSR and its stimulation of digestive processes even when there are relatively low levels of [Ca\(^{2+}\)]\(_i\). Moreover, as reported in clinical studies, there are 33 disease-related variants near Ca\(^{2+}\)-binding site 1 associated with receptor activation or inactivation and, in some cases, with reduced cooperativity (15). Our work suggests that it is likely that such mutations disrupt the molecular connectivity encoded in the receptor and provide a better understanding of the molecular basis of some of the CaSR-related clinical disorders. Although the circulating levels of Ca\(^{2+}\) and l-Phe in vivo are lower than in the in vitro experiments, the discrepancy noted here (2–3-fold for the WT receptor for Ca\(^{2+}\)) is substantially less than that of more classical hormone receptor systems. For the cloned parathyroid hormone receptor, for example, the \(K_D\) values for activation of adenylate cyclase and stimulation of PLC, are 1 and 20–50 nM, respectively, whereas the normal circulating levels of parathyroid hormone are \(\sim 1\)–7 pm, i.e., resulting in a \(\sim 100\)-fold discrepancy to even a \(\sim 1,000\)-fold discrepancy between in vivo and in vitro results (64). Our finding of the capacity of l-Phe to rescue disease-linked mutations suggests the possibility of enhancing the activities of such mutant receptors using calcimimetics of various types as pharmacotherapy. Thus, our results provide insights into key factors regulating the overall activity of the receptor, which can lay the foundation for a new generation of therapeutics and drugs.

In addition to the Ca\(^{2+}\)-sensing receptor, [Ca\(^{2+}\)]\(_i\) regulates 14 of the other members of the family C GPCRs, including the...
L-Phe and Ca\(^{2+}\) Promote CaSR Functional Positive Cooperativity

mGluRs, GABA\(_{B}\) receptors, and receptors for pheromones, amino acids, and sweet substances (1, 5, 10, 16, 54–56, 65). The observed molecular connectivity centered at predicted calcium-binding site 1 of the CaSR, which is adjacent to an amino acid-binding pocket at the hinge region of the receptor, may be shared by other members of the family C GPCRs to facilitate understanding, exhibited by the two agonists may be further extended to other members of the family C GPCRs to facilitate understanding of the molecular basis for related human disorders and the development of new therapeutic strategies.

In summary, our present study provides a mechanistic view of the interplay among extracellular Ca\(^{2+}\), amino acids and the CaSR via molecular connectivity that modulates the positive homotropic and heterotropic cooperativity of CaSR-mediated intracellular Ca\(^{2+}\) signaling. The positive cooperative coactivation of the CaSR by Ca\(^{2+}\) and L-Phe and the importance of the positive homotropic and heterotropic cooperativity, respectively, exhibited by the two agonists may be further extended to other members of the family C GPCRs to facilitate understanding of the molecular basis for related human disorders and the development of new therapeutic strategies.

Acknowledgments—We thank Dr. Yubin Zhou, Dr. Michael Kirberger, Dr. Rajesh Thakker, Katheryn Lee Meenach, and Xiaojun Xu for critical review and assistance.
